Preface

The scope of the *Encyclopedia of Earthquake Engineering* covers the interaction between earthquake events and our engineering installations and infrastructures. It is expected to range over buildings, foundations, underground constructions, lifelines and bridges, roads, embankments, and slopes. Although a plethora of references exist in the context of treating/addressing individual earthquake engineering topics, there is no literature dealing with earthquake engineering in a comprehensive, versatile, and unified manner. In this regard, the extreme event of an earthquake has a multifaceted impact on a variety of activities. These include day-to-day operations of public and private services which have greatly increased their exposure to risk.

The Encyclopedia is designed to inform technically inclined readers about the ways in which earthquakes can affect engineering installations and infrastructures and how engineers would go about designing against, mitigating, and remediating these effects. It is also designed to provide cross-disciplinary and cross-domain information to domain experts. Specifically, the proposed work introduces a coupling between traditional topics of earthquake engineering, such as geotechnical/structural engineering, topics of broader interest such as geophysics, and topics of current and emerging value to industrial applications, such as risk management. In this regard, risk management is included in a comprehensive manner, which addresses the dimension and complexity of earthquake hazards. This elucidates the vital connection of the technical contents to the societal context. The main benefit of the Encyclopedia is its breadth of coverage to provide quick information on a substantial level to virtually all groups of readers from academia, industry, and the general population who would like to find out more in the area of earthquake engineering.

Overall, this work is a concerted effort to provide with a holistic perspective on earthquake engineering-related issues of recent currency. Its innovative, modular, and continuously updated form facilitates a potent, self-contained, and readily accessible exposition of multi/interdisciplinary elements in the broad field of earthquake engineering, thus enabling the researcher/practitioner/designer to identify links and potential future research themes in an efficient and timely manner.

Acknowledgments

The Editors greatly appreciate the effort made by the section editors, the contributions of the authors related to work of high standards, as well as the determination of the reviewers to preserve high quality levels. Further, the Editors would like to thank Springer for its guidance and leadership on making this great project a reality.

About the Editors

Michael Beer Institute for Computer Science in Civil Engineering, Gottfried Wilhelm Leibniz University Hannover, Hannover, Germany

Michael Beer, Dr.-Ing., obtained his degrees in civil engineering from the Technical University of Dresden, Germany. He worked at Rice University as a fellow of the Alexander von Humboldt-Foundation and held a faculty position at National University of Singapore in the Department of Civil and Environmental Engineering. Dr. Beer was a professor and the founding director of the Institute for Risk and Uncertainty in the University of Liverpool. He is now professor and head of the Institute for Computer Science in Civil Engineering at Gottfried Wilhelm Leibniz University Hannover, Germany, as well as a guest professor in Tongji University, Shanghai, China and a part-time professor in the Institute for Risk and Uncertainty, University of Liverpool.

Ioannis A. Kougiumtzoglou Department of Civil Engineering & Engineering Mechanics, Columbia University, New York, NY, USA

Ioannis Kougiumtzoglou, Ph.D., obtained his M.Sc. and Ph.D. degrees from the civil and environmental engineering department of Rice University, Texas, USA. He also holds a five-year Diploma in Civil Engineering from the National Technical University of Athens (NTUA), Greece, and is a professional/chartered civil engineer in Greece. He is currently an assistant professor at the Department of Civil Engineering and Engineering Mechanics at Columbia University, New York, USA.

Edoardo Patelli Institute for Risk & Uncertainty and Centre for Engineering Sustainability, Liverpool, UK

Edoardo Patelli, Ph.D., obtained his degrees in nuclear engineering and Ph.D. in radiation science and technology from the Politecnico di Milano, Italy. He worked at the Institute for Engineering Mechanics, University of Innsbruck, Austria. He is currently a lecturer in uncertainty and engineering at the Institute for Risk and Uncertainty at the University of Liverpool, UK, and the head of computational technology for the EPSRC Centre for Doctoral Training in Risk and Uncertainty Quantification. Patelli is also an honorary member of the National Tsing Hua University, Taiwan.

Siu-Kui Au Institute for Risk & Uncertainty and Centre for Engineering Dynamics, Liverpool, UK

Siu-Kui Au, Ph.D., is a chartered civil engineer in Hong Kong and obtained his B.Eng. and M.Phil. from the Hong Kong University of Science and Technology and Ph.D. from the California Institute of Technology (USA). He is currently a professor of uncertainty, reliability and risk at the Institute for Risk and Uncertainty. Before joining Liverpool he has held faculty positions at the Nanyang Technological University (Singapore) and the City University of Hong Kong. He was a visiting professor at the Tokyo City University (Japan) and Wuhan University (China).

Active control; Control algorithms; Hybrid control; Semi-active control; Structural control

Introduction

Structural control of seismically excited buildings and other civil structures has attracted considerable attention in recent years. The objective of this entry is to present how seismic design of structures can benefit from the structural control concepts and applications. For this purpose, control theory as applied in other engineering disciplines is adjusted and appropriately modified, where needed, in order to propose integrated control procedures suitable for civil structures subjected to earthquake excitation.

Two approaches can be taken to help buildings withstand seismic excitations. The first involves designing the structure with sufficient strength, stiffness, and inelastic deformation capacity to withstand an earthquake. The choice of material used in construction and the soil beneath the structure are important factors that influence structural vibration and the amount of damage. Because this approach relies on the inherent strength of the structure to dissipate the seismic energy, a certain level of inelastic deformation and associated damage has to be accepted. The second approach relies on using control devices in order to reduce the forces acting on the structure, aiming at reducing all quantities of structural response, that is, floor accelerations, velocities, and displacements. Control systems are categorized according to their energy requirements as passive, active, semi-active, and hybrid. In order to apply a control approach, appropriate control devices are needed. These devices are capable of altering the dynamic characteristics of a structure in real time or applying direct or indirect control forces to the structure, in order to reduce its response. These devices operate as instructed by suitably designed control algorithms.

Several available control algorithms are applied to control structures, many of which were developed by researchers in other fields like electrical or mechanical engineering. However, electrical and mechanical devices are

Fig. 4 Structure with semi-active control devices

different from buildings as far as their structural behavior is concerned. The former, in most cases, are mechanisms, while the latter are constructions with a high degree of redundancy. Moreover, in the control of electromechanical devices, the loading is known a priori and is usually harmonic, while for buildings the earthquake loading is unknown and contains a multitude of frequencies. Thus, there is a need of selecting among existing algorithms those that are suitable for the control of buildings and then modifying them accordingly. Along these lines, a common feature of all control strategies that are presented here is that they are applied to structures excited at their base by incoming earthquake waves.

Structural Control (Passive, Active, Semi-active, Hybrid), Corresponding Control Devices, and Practical Applications

Structural control systems fall into four basic categories: passive, active, semi-active, and hybrid control (Soong 1990; Soong and Spencer 2002). These structural control systems are presented in Figs. 1, 2, 3, 4, and 5 below.

Passive Control

Passive control devices are devices that do not require power to operate. Examples of passive devices are base isolation, tuned mass dampers (TMD), tuned liquid dampers (TLD), metallic yield dampers, viscous fluid dampers, and

Actively and Semi-actively Controlled Structures Under Seismic Actions: Modeling and Analysis,
Fig. 5 Structure with hybrid control devices

friction dampers. They dissipate energy using the motion of the structure to produce relative movement within the control device or to alter the dynamic properties of the structure (damping, natural frequencies), so that the earthquake action will be minimized. Since they do not inject energy into the system, they are stable devices. Another advantage of such devices is their low maintenance requirements and the fact that they are unaffected by potential interruptions in power supply. These systems are well understood and well accepted by the engineering community as a means for mitigating the effects of dynamic loadings, such as strong earthquakes and high winds. However, such passive devices have the limitation of not being able to adapt to structural changes and to different earthquake excitations. Active, semi-active, and hybrid control systems aim at addressing these shortcomings.

Active Control

Active control strategies have been developed in the 1990s, (Soong 1990; Housner et al. 1997); they operate by using external energy supplied by actuators to impart forces on the structure. The appropriate control action is determined based on measurements of the structural response. Active control devices include the active tendon system (Abdel-Rohman and Leipholz 1983), the active bracing system (Reinhorn et al. 1989), and the active tuned mass damper (Abdel-Rohman and Leipholz 1983).

The most famous active control device is the active mass damper (AMD), which uses a mass–spring–damper system combined with

an actuator that moves the mass as needed to increase the amount of damping and the operational frequency range of the device. The first implementation of this control method, and of active control in general, was performed in 1989 in the Kyobashi Seiwa building, Tokyo, Japan, by Kajima Corporation (Kobori et al. 1991). Other applications of such devices include the Applause Tower (Hankyu Chayamachi building) in Osaka, Japan; the Riverside Sumida Central Tower, in Tokyo, Japan; the Nanjing Communication Tower, in Nanjing, China; and the Shin-Jei building in Taipei, Taiwan (Spencer and Nagarajaiah 2003).

Active control devices require considerable amount of external power to operate actuators that supply a control force to the structure. Such power may not always be available during seismic events. Another drawback is that due to their capacity to add energy to the system, they may destabilize it. Cost and maintenance of such systems is also significantly higher than that of passive devices. On the other hand, they are more effective than passive devices because of their ability to adapt to different loading conditions and to control different modes of vibration. Housner et al. (1997) point out the importance of system integration in the design and development of active control systems. Not only is it necessary to consider the individual components of a control system, but the system as a whole must be understood, including the structure, control devices, sensors, and computer control system. Błachowski (2007) uses model-based predictive control to reduce the vibration for guyed mast.

Fig. 6 Variable-orifice damper and controllably fluid damper

Actively and Semi-actively Controlled Structures Under Seismic Actions: Modeling and Analysis,
Fig. 7 Friction semi-active device (a) and semi-active tuned liquid column damper (b)

Semi-active Control

Semi-active control devices offer the adaptability of active ones without requiring such high power, since external power is only used to change the device's properties, such as damping or stiffness, and not to generate a control force (Symans et al. 1994). In fact, many semi-active devices can operate on battery power, which is critical during seismic events, when the main power source to the structure may fail.

A semi-active control device cannot inject energy into the controlled system (structure and device) but has properties that can be varied in real time in order to reduce the response of a structural system (Housner et al. 1997). Changes in mechanical properties of the device are based on feedback from measured response and/or ground excitation. Therefore, in contrast to active control devices, semi-active ones do not destabilize the structural system. They offer

stability and reliability, since they function as passive devices in case of power failure (Soong and Spencer 2002). A lot of studies indicate that appropriately designed semi-active systems perform significantly better than passive ones. Moreover, they perform better than active systems for a variety of dynamic loading conditions.

Examples of such devices include variable orifice fluid dampers, controllable friction devices, variable stiffness devices, controllable liquid dampers, and controllable fluid dampers (Figs. 6 and 7). A variable orifice fluid damper uses an electromechanically variable orifice to alter the resistance to flow of a conventional hydraulic fluid (Feng and Shinozuka 1992; Constantinou et al. 1993).

A semi-active controllable fluid device is a combination of dampers with fluids that have the ability to reversibly change their viscosity. The two controllable fluids used in structural

control devices are electrorheological (ER) and magnetorheological (MR) fluids. They consist of dielectric polarizable (electrorheological, ER fluids) or magnetically polarized (magnetorheological, MR fluids) particles suspended in an oil medium. They have the ability to reversibly change from viscous fluids to semi-solids with controllable yield strength in milliseconds, with the application of an electrical or magnetic field, respectively. This property makes them ideal for use in controllable dampers. The advantage of controllable fluid devices is that they contain no moving parts other than the piston, which makes them very reliable and very easy to maintain. Moreover, they require low power to operate.

The discovery of both ER and MR fluids dates back to the late 1940s (Winslow 1947). ER fluid dampers have been developed, modeled, and tested for civil engineering applications (Erhrogott and Marsi 1992, 1993; Makris et al. 1995). Work on MR devices have been done by Spencer et al. (1997), Soong and Spencer (2002), Spencer and Nagarajaiah (2003), Carlson et al. (1995), and Dyke et al. (1996c–f).

Other semi-active devices use the force generated by surface friction to dissipate energy in a structural system.

Other types of semi-active control devices use the dynamic motion of a sloshing fluid or a column of fluid to reduce the response of a structure. These liquid dampers are the evolution of passive tuned sloshing dampers (TSD) and tuned liquid column dampers (TLCD). The TSD uses the liquid in a sloshing tank to add damping to the structural system. Similarly, in a TLCD the moving mass is a column of liquid, which is driven by the vibrations of the structure. These passive systems are not very effective for varying loading conditions. To improve their effectiveness, a semi-active device based on the passive TSD has been proposed, in which the length of the sloshing tank, thus also the properties of the device, and therefore its natural frequency can be changed. Similarly, in semi-active devices based on a TLCD, a variable orifice within the liquid column is used, or the cross section of the sloshing tank is changed.

Semi-active tuned mass dampers are similar to TMDs, but with the capability of varying their level of damping. They are mainly used for wind vibration reduction. Another type of semi-active TMD is the semi-active variable stiffness tuned mass damper (SAIVS-TMD), where the stiffness is also controllable. Their performance is similar to that of AMDs but with less power consumption.

Variable stiffness control devices have the ability to modify the structure's stiffness and therefore its natural frequency to avoid resonant conditions. These systems have been studied by Kobori et al. (1993). They are installed in bracing systems, and with opening or closing a valve, they allow the connection between the brace and beam, thus changing the building stiffness and therefore its frequency, to avoid resonance with the incoming earthquake. Their energy operation is very low, and they are designed so that in the case of power failure, the connection is automatically closed and the structure's stiffness is increased.

The first full-scale application of semi-active control was the installation of variable stiffness devices on both sides of the Kajima Technical Research Institute.

Hybrid Control

Hybrid control refers either to a combination of passive and active systems or, more commonly, to a combination of passive with semi-active systems, aiming at lowering the forces required by active or semi-active systems, respectively. One such device is the hybrid mass damper (HMD), which combines tuned mass dampers with active actuators. The actuator force is only used to increase efficiency and robustness to changes in structural dynamic characteristics. Also in the category of hybrid mass dampers is the active–passive composite tuned mass damper (APTMD) developed by Ohruai et al. (1994) and named DUOX. This device is composed of an active mass damper mounted on a tuned mass damper, Fig. 8. During structural motion, the mass of the AMD is driven in the opposite direction of the TMD, therefore magnifying the motion of the passive device. When the building

Actively and Semi-actively Controlled Structures Under Seismic Actions: Modeling and Analysis,
Fig. 8 Simplified diagram of DUOX control system

deformation stops, the AMD is used to suppress useless motion of the TMD.

Base isolation systems are passive systems, and they do not have the ability to adapt and change their properties in different external excitation (e.g., near- or far-fault excitation). With the addition of an active or semi-active control device to a base-isolated structure, a higher level of performance can be achieved without a substantial increase in the cost. This thought has led to another type of hybrid control system, referred to as hybrid seismic isolation, consisting of active or semi-active devices introduced in base-isolated structures (see Fig. 9). Although base isolation has the ability to reduce interstory drifts and structural accelerations, it increases base displacement, hence the need for an active or semi-active device. In addition, a semi-active friction-controllable fluid bearing has been employed in parallel with a seismic isolation system (Feng and Shinozuka 1992; Sriram et al. 2003).

Hybrid control strategy, HMD, was first implemented in 1993, in the Ando Nishikicho Building in Tokyo, Japan. During strong winds or moderate earthquakes, when the structure's first mode of vibration can be considered dominant, the control system will simply act as a passive device. However, in the case of a stronger earthquake, where the ground excitation is spread over a wider frequency band and

Actively and Semi-actively Controlled Structures Under Seismic Actions: Modeling and Analysis,
Fig. 9 Hybrid control system

the first mode of vibration may no longer be dominant, the actuator is activated to compensate the response due to higher modes.

A combination of passive and active control systems has been applied to USC University Hospital and includes five of the six buildings of the medical center. Both linear and high damping rubber bearings were chosen for the base isolation, to provide lateral stiffness,

which controls natural vibration period and hysteretic damping. Active control is accomplished by the placement of viscous damping devices at the base of the structure to provide velocity-dependent damping, which controls the overall building displacements.

Structures equipped with hybrid mass dampers are the Kansai International Airport in Osaka, Japan; the Mitsubishi Heavy Industry in Yokohama, Japan; and the RIHGA Royal Hotel in Hiroshima, Japan. An interesting device can be found in the Shinjuku Park Tower consisting of a V-shaped HMD developed by the Ishikawajima-Harima Heavy Industries. This device has an easily adjustable fundamental period.

An application of hybrid control carried out by Lin et al. (2007) included a series of large-scale experimental tests conducted on a mass equipped with a hybrid controlled base isolation system, consisting of a rolling pendulum system (RPS) and a 20-KN magnetorheological (MR) damper. The 12-t mass and its hybrid isolation system were subjected to various intensities of near-fault and far-fault earthquakes on a large shake table. The results showed that a combination of rolling pendulum system and an adjustable MR damper can provide robust vibration control for large civil engineering structures that need protection from a wide range of seismic events.

A benchmark smart base-isolated eight-story building structure has been presented by Narasimhan et al. (2003), similar to existing buildings in Los Angeles, California. The base isolation system includes both linear and nonlinear bearings and control devices. Design and implementation of active semi-active and hybrid systems can also be found in the work of (Chu et al. 2005; Yi et al. 2001).

Modeling

Continuous and Discrete Control

The equation of motion of a controlled structural system with n degrees of freedom u_i , subjected to an earthquake excitation a_g , is given by Eq. 1:

$$\mathbf{M}\ddot{\mathbf{U}}(t) + \mathbf{C}\dot{\mathbf{U}}(t) + \mathbf{K}\mathbf{U}(t) = -\mathbf{M}\mathbf{E}a_g(t) + \mathbf{E}_f\mathbf{F}(t) \quad (1)$$

where $\mathbf{M}$, $\mathbf{C}$, $\mathbf{K}$ denote the mass, damping, and stiffness matrixes of the structure, respectively, $\mathbf{E}$, $\mathbf{E}_f$ are the location matrix for the earthquake and the control forces on the structure, and $\mathbf{F}(t)$ is the control force matrix which is applied to the structure.

In the state space approach, Eq. 1 can be written as follows:

$$\begin{aligned} \dot{\mathbf{X}}(t) &= \mathbf{A}\mathbf{X}(t) + \mathbf{B}_g a_g(t) + \mathbf{B}_f \mathbf{F}(t) \\ \mathbf{Y}(t) &= \mathbf{C}\mathbf{X}(t) + \mathbf{D}\mathbf{F}(t) + \mathbf{v} \end{aligned} \quad (2)$$

The matrixes $\mathbf{X}$, $\mathbf{A}$, $\mathbf{B}_g$, $\mathbf{B}_f$ are given by

$$\begin{aligned} \mathbf{X} &= \begin{bmatrix} \mathbf{U} \\ \dot{\mathbf{U}} \end{bmatrix}_{2n \times 1}, \mathbf{A} = \begin{bmatrix} \mathbf{O} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix}_{2n \times 2n}, \\ \mathbf{B}_g &= \begin{bmatrix} \mathbf{O} \\ -\mathbf{E} \end{bmatrix}_{2n \times 1}, \mathbf{B}_f = \begin{bmatrix} \mathbf{O} \\ \mathbf{M}^{-1}\mathbf{E}_f \end{bmatrix}_{2n \times 1} \end{aligned} \quad (3)$$

The matrixes $\mathbf{Y}$, $\mathbf{C}$, $\mathbf{D}$, and $\mathbf{v}$ are the output states, the output matrix, the feed forward control force matrix, and the noise matrix, respectively. In the case where the output variables are the same with the states of the system and there is no application of the control forces to the output variables, the matrixes $\mathbf{C}$, $\mathbf{D}$ are the identity and zero matrix, respectively. The noise matrix depends on the sensor that is used to measure the response of the system. The above equation can be solved by any numerical technique for differential equations, like an explicit Runge–Kutta formula, the Dormand–Prince pair, Bogacki–Shampine, and Adams–Bashforth–Moulton PECE solver.

The continuous solution of Eq. 3 is

$$\begin{aligned} \mathbf{x}(t) &= \mathbf{e}^{\mathbf{A}(t-t_0)} \mathbf{x}_0 + \int_{t_0}^t \mathbf{e}^{\mathbf{A}(t-\tau)} (\mathbf{B}_f \mathbf{F}(\tau) + \mathbf{B}_g a_g(\tau) \\ &\quad + \mathbf{B}_p p(\tau)) d\tau \end{aligned} \quad (4)$$

Equation 4 is applied assuming that the displacement or velocity and control force are continuous

functions of time. This does not apply to a real control situation, where the control force is calculated by observed values of displacement, velocity, or acceleration at discrete time intervals. For discrete description, the total time is divided into small intervals $t_0-t_1, t_1-t_2, \dots, t_n-t_f$, with time interval Δt .

An approximate solution of Eq. 3 between two points of time t_j and $t_{j+1} = t_j + \Delta t$ is obtained making the following substitutions in the above continuous solution Eq. 4 and editing the exponential integral:

$$\begin{aligned} t &= t_{j+1} \quad t_0 = t_j \\ \mathbf{X}(t_j) &= \mathbf{X}_j \quad \mathbf{F}(\tau) = \mathbf{F}(t_j) = \mathbf{F}_j \\ p(\tau) &= p(t_j) = p_j \quad a_g(\tau) = a_g(t_j) = a_{g_j} \end{aligned} \quad (5)$$

$$\mathbf{X}_{j+1} = e^{A\Delta t} \mathbf{X}_j + \mathbf{A}^{-1} (e^{A\Delta t} - \mathbf{I}) [\mathbf{B}_F \mathbf{F}_j + \mathbf{B}_g a_{g,j} + \mathbf{B}_p p_j] \quad (6)$$

The above equation provides an estimate of the response at time t_{j+1} based on values of the response at previous time t_j . The first term in the right-hand side represents the free oscillation response (transient state), while the other terms provide the response to load during time Δt (steady state). The above approach can be applied to adaptive systems (term in civil structures: material nonlinearity), wherein the stiffness and damping constants vary with time, while the mass is maintained constant. In that case matrix $\mathbf{A}$ is altered over time but remains constant during the interval Δt . In this case Eq. 6 becomes

$$\mathbf{X}_{j+1} = e^{A_j \Delta t} \mathbf{X}_j + \mathbf{A}_j^{-1} (e^{A_j \Delta t} - \mathbf{I}) [\mathbf{B}_F \mathbf{F}_j + \mathbf{B}_g a_{g,j} + \mathbf{B}_p p_j] \quad (7)$$

where

$$k(t) = k(t_j) = k_j \quad \mathbf{A}(t) = \mathbf{A}(t_j) = \mathbf{A}_j \quad c(t) = c(t_j) = c_j \quad (8)$$

The feedback control force in discrete form is

$$\begin{aligned} \mathbf{F}_j &= -\mathbf{K}_{f,j} \mathbf{X}_j, \quad t_j \leq t \leq t_{j+1} \\ \mathbf{K}_{f,j} &= [k_d(t_j) k_v(t_j)] \end{aligned} \quad (9)$$

Replacing into Eq. 7 yields

$$\begin{aligned} \mathbf{X}_{j+1} &= (e^{A_j \Delta t} - \mathbf{A}_j^{-1} (e^{A_j \Delta t} - \mathbf{I}) \mathbf{B}_F \mathbf{K}_f) \mathbf{X}_j \\ &\quad + \mathbf{A}_j^{-1} (e^{A_j \Delta t} - \mathbf{I}) [\mathbf{B}_g a_{g,j} + \mathbf{B}_p p_j] \end{aligned} \quad (10)$$

The output response is obtained by starting from time t_0 , when the response is known, and calculating subsequent time points. The critical issue here is the determination of time Δt and the distribution of stiffness and feedback parameters k_v and k_d .

Linear and Nonlinear Control

In Eq. 1, the change of the material properties change during loading leads to changes in the stiffness matrix. Then, the differential equations become nonlinear:

$$\mathbf{M}\ddot{\mathbf{U}}(t) + \mathbf{C}\dot{\mathbf{U}}(t) + \mathbf{F}_s(\mathbf{U}(t)) = -\mathbf{M}\mathbf{E}a_g(t) + \mathbf{E}_f \text{sat} \mathbf{F}(t - t_d) \quad (11)$$

In this case the nonlinearity originates from the structure and is described as material nonlinearity.

When the equation of motion is formulated in the deformed configuration to account for the structure's flexibility and associated large displacements, then equation of motion (1) also becomes nonlinear; the nonlinearity also originates from the structure, but now it is described as geometric nonlinearity.

When the control force, $\mathbf{F}$, is a linear function of the response of the structure, then the above equations of motion (1) are linear differential equations, and the control is said to be linear. When the control force is not a linear function, then Eq. 1 are nonlinear differential equations, and the nonlinearity originates from the control force.

Thus, the source of nonlinearity could be either from the structure or from the control force. In Table 1 below, the possible cases are presented.

Practical Considerations

Over the past few decades, various control algorithms and control devices have been developed, modified, and investigated by various groups of researchers. Several well-established algorithms

Actively and Semi-actively Controlled Structures Under Seismic Actions: Modeling and Analysis,
Table 1 Linear and nonlinear cases of analysis

Control force	Structure		
	Linear	Nonlinear	
		Material	Geometric
Linear	Linear structure, linear control	Nonlinear structure, linear control	Nonlinear structure, linear control
Nonlinear	Linear structure, nonlinear control	Nonlinear structure, nonlinear control	Nonlinear structure, nonlinear control

in control engineering have been introduced to control structures. While many of these structural control strategies have been successfully applied, technological problems and challenges relating to time delay, saturation capacity effects, cost, reliance on external power, and mechanical complexity and reliability during the life of the structure have delayed their widespread use, and relatively few actual structures are equipped with control systems.

Another practical issue that influences the effectiveness and the reliability of the proposed control algorithms is the effect of the position of control forces. The selection of locations of control forces influences the location matrix, $\mathbf{B}_f$ of the control force in the differential equation of motion of controlled structure. Thus, this effect can be investigated numerically by parametric variation of the location matrix.

Other practical effects include control–structure interaction, actuator dynamics, and digital control implementation. The reliability of applied semi-active structural control systems and practical applications and verification for active and semi-active vibration control of buildings in Japan have been studied by Ikeda (2009).

Time Delay–Saturation Capacity

Two practical issues that influence the effectiveness and the reliability of the proposed control algorithms are time delay and saturation of the control force. Those parameters come into consideration by solving the differential equation of

motion as a delay differential equation with saturation effects. The expected negative influence of those parameters should be considered in the design process. Thus, there is a need to take them into account in the numerical simulations before the installation of the control system on the real building.

The equation of motion (1) of a controlled structural system considering time delay and saturation becomes

$$\mathbf{M}\ddot{\mathbf{U}}(t) + \mathbf{C}\dot{\mathbf{U}}(t) + \mathbf{K}\mathbf{U}(t) = -\mathbf{M}\mathbf{E}\mathbf{a}_g(t) + \mathbf{E}_f \text{sat}\mathbf{F}(t - t_d) \quad (12)$$

$\text{sat}\mathbf{F}$ is the saturated control force matrix which is applied to the structure with time delay t_d and is given as

$$\text{sat}\mathbf{F}(t - t_d) = \begin{cases} \mathbf{F}(t - t_d) & \mathbf{F}(t - t_d) < \mathbf{F}_{\text{allowable}} \\ \mathbf{F}_{\text{allowable}} & \mathbf{F}(t - t_d) > \mathbf{F}_{\text{allowable}} \end{cases} \quad (13)$$

$\mathbf{F}_{\text{allowable}}$ is the maximum capacity of the control device. In the state space approach, Eq. 12 can be written as follows:

$$\begin{aligned} \dot{\mathbf{X}}(t) &= \mathbf{A}\mathbf{X}(t) + \mathbf{B}_g \mathbf{a}_g(t) + \mathbf{B}_f \text{sat}\mathbf{F}(t_d - t) \\ \mathbf{Y}(t) &= \mathbf{C}\mathbf{X}(t) + \mathbf{D}\mathbf{F}(t_d - t) + \mathbf{v} \end{aligned} \quad (14)$$

This equation can be solved by the technique of delay differential equation, or one can use the following transformation

$$\mathbf{Z}(t) = \mathbf{X}(t) + \int e^{-\mathbf{A}(\eta+t_d)} \mathbf{B}_f \mathbf{F}(t + \eta) d\eta \quad (15)$$

Then:

$$\begin{aligned} \dot{\mathbf{Z}}(t) &= \mathbf{A}\mathbf{Z}(t) + \mathbf{B}_g \mathbf{a}_g(t) + \mathbf{B}(\mathbf{A})\mathbf{F}(t) \\ \mathbf{B}(\mathbf{A}) &= e^{-\mathbf{A}t_d} \mathbf{B}_f \end{aligned} \quad (16)$$

Since the entire control process involves measuring response data, computing control forces through an appropriate algorithm, transmitting data and signals to actuators, and activating the actuators to a specified level of force, time delays

arise and cannot be avoided. The problem of time delay in the active control of structural systems has been investigated from many scientists and engineers. The stability of the structure could be lost due to time delay, and two ways of time-delay compensation can be followed. In the first the gain matrix is redesigned considering the presence of time delay, while in the second low-pass filters are used to filter the velocity measurements from the frequency components of the high-order modes. In the first case, the structure could remain unstable when using control moments as control actions, while in the second a number of vibration modes can be controlled and compensated for time delay, but the higher-order modes remain uncontrolled. Time delay can be compensated with Pade approximations. The allowable time delay is related with natural period and feedback gain. The maximum allowable time delay is decreased with decrease in natural period of the structure, as well as with increase in active damping. Under earthquake excitations, simulation results for the response of multi-degree of freedom structures indicated that the degradation of the control performance due to fixed time delay is significant when time delay is close to a critical value. The time-delay problem is more serious for structures with closely spaced vibration modes.

In optimal control of linear systems, time delay is considered at the very beginning of the control design, and no approximations and estimations are made in the control system. Thus, the system performance and stability can be guaranteed. Instability in the response might occur only if a system with time delay is controlled by an optimal controller that was designed with no consideration of time delay.

For pole assignment algorithm, through varied location of the controlled poles, the control system shows variable performance. However, the locations of the controlled pole pairs should be carefully specified and checked according to the characteristics of the system. Analytical expressions of limiting values of time delay for single degree of freedom systems were derived by Connor (2003); however, such expressions were very difficult to obtain for multi-degree of

freedom systems. Casciati et al. (2006) have taken into consideration the time-delay effect solving numerically delayed differential equations. All of these studies demonstrate how important the issue of time delay is in structural control and how it may result in a degradation of the control performance and may even drive the controlled structure to become unstable. Most studies show that time delays influence negatively the control system; therefore, they should be kept small compared to the fundamental period of vibration of the system and should, if possible, be eliminated.

The second important practical problem is the saturation of the control force. Actuator saturation occurs when the force which is given by the control algorithm is larger than its designed peak capacity. Failure to account for this nonlinear effect can decrease the efficiency of the control system and possibly drive the structure to become unstable. Most control algorithms are linear, assuming that there is no limit in the magnitude of the control force. However, maximum capacity of the control devices is limited. Therefore, designing controllers to account for the bounded nature of the devices is desirable.

The two issues of time delay and saturation of the control device are, in most cases, considered and studied separately. However, in the application of real control systems, these two issues act simultaneously. Pnevmatikos and Gantes (2011) investigated a combined effect of the nonlinear phenomena of bounded capacity of the actuators and time delay of the system, acting simultaneously during the control process, on the systems response. They proposed limits for pair of time delay and saturation capacity that can be used in the design process of controlled structures.

Spillover Effect

With the discretization of a continuous system to a finite degree of freedom system, some information is lost since a real physical system has infinite natural mode shapes and frequencies, while the discrete systems contain some of them. Those frequencies that are not included in the discrete model are called remaining frequencies or

residual modes. If flexible structure is modeled, there is a danger that the control based on a reduced model is destabilized due to the high remaining modes which are not included in the model. Balas (1978) defined and studied the above phenomenon, which is called spillover effect. Meirovich (1990) investigated observation spillover (measurements at some points, without having the total picture of the response) and stated that this can be really dangerous for the controlled structures.

Controllability: Observability

Controllability of system deals with the number of control positions and degrees of freedom of the structure. When the number of control positions is equal to the number of degrees of freedom of the structure, then full control of the system is achieved. In that case, the building performs a rigid body motion, following the imposed ground motion, without relative displacements between the floors. It was also shown that with reduced number of control forces, positioned at appropriate locations, which is a more realistic choice for real buildings, the response can be reduced to a satisfactory level. Observability is associated with measurement positions in the structure to degrees of freedom of the structure. When the measurement positions are equal to the number of degrees of freedom of the structure, then full-state feedback is achieved. Otherwise, feedback with an observer is performed.

Collocated and Not Collocated Control/ Centralized and Decentralized Control

A definition of collocation and centralization is given by Casciati et al. (2006). A control system is collocated when the force generated by an actuator at a point of the structure is measured by a force sensor at the same location, in other words when the actuator and sensor are connected exactly at the same location. Otherwise, control is non-collocated.

A control system is centralized if it is managed by a unique computer that receives the inputs from all sensors and gives the command output to all actuators. The system is decentralized

(noncentralized) if the control system is managed by several computers that take the input from some specific sensors and give the command output to some actuators. It is thus possible that a noncentralized system could be collocated or that a centralized system could be non-collocated.

Analysis

Control Strategies and Algorithms

Several well-established algorithms in control engineering have been introduced to control structures, such as optimal control, LQR or LQG, pole assignment, sliding mode control, H_2 and H_∞ , fuzzy control, and many others. The most suitable algorithms for structural application and the practical considerations that should be taken into account are described by Soong (1990) and Casciati et al. (2006).

Optimal Control, LQR, or LQG

Research in structural control has focused on a variety of control algorithms based on different control design criteria. Some algorithms originate from direct applications of optimal control theory. Some others, however, are specifically proposed for civil engineering structural control applications.

The control force, $\mathbf{F}$, can be applied directly or indirectly to the structure. The way in which the control force is calculated is determined from the control algorithm that is used. If the control force is calculated by linear state feedback:

$$\mathbf{F} = -\mathbf{G}_1 \mathbf{U} - \mathbf{G}_2 \dot{\mathbf{U}} = -[\mathbf{G}_1 \ \mathbf{G}_2] \begin{bmatrix} \mathbf{U} \\ \dot{\mathbf{U}} \end{bmatrix} = -\mathbf{G} \mathbf{X} \quad (17)$$

$\mathbf{G}$ is the gain matrix, which is calculated according to the desired poles of the controlled system. Replacing the force $\mathbf{F}$ into Eq. 1 or 2, the controlled system can be described by

$$\mathbf{M} \ddot{\mathbf{U}}(t) + (\mathbf{E}_f \mathbf{G}_2 + \mathbf{C}) \dot{\mathbf{U}}(t) + (\mathbf{E}_f \mathbf{G}_1 + \mathbf{K}) \mathbf{U}(t) = -\mathbf{M} \mathbf{E} a_g(t) \quad (18)$$

$$\dot{\mathbf{X}} = (\mathbf{A} - \mathbf{B}_f \mathbf{G})\mathbf{X} + \mathbf{B}_g a_g \quad (19)$$

$$\mathbf{X}(t_0) = \mathbf{X}(0) = \mathbf{X}_0$$

From the above equation, it is seen that control of structures can be achieved by changing the stiffness or damping and consequently the dynamic characteristics of the building in a direct or indirect way, depending on the device that is used. The question is how to estimate the control force or the matrix $\mathbf{G}$ in such a way that the desired dynamic characteristics for the controlled building are achieved.

The feedback matrix can be calculated based on optimal control theory like linear quadratic regulator, LQG. Optimal control methods are based on the concept of minimizing a cost criterion. The criterion of cost, represented by J , has a common format:

$$J = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{t_0}^{t_f} \mathbf{e}^T(t) \mathbf{e}(t) dt \quad (20)$$

where

$$\mathbf{e}(t) = \mathbf{X}(t) - \mathbf{X}^*(t) \quad (21)$$

$\mathbf{e}(t)$ is the error between the desired behavior, $\mathbf{X}^*$, and the actual behavior, $\mathbf{X}$, of the system.

The scope of the problem of optimal control is to determine a control force, $\mathbf{F}(t)$, such that it determines the behavior of the control system to minimize some cost criterion while satisfying some physical constraints of the system. The cost criterion is usually formulated so as to express a quantity to have physical significance, e.g., displacement and energy. A specialized form of cost criterion of Eq. 20 is as follows:

$$J = \theta[\mathbf{X}(t), t] \Big|_{t=t_0}^{t=t_f} + \int_{t_0}^{t_f} \phi[\mathbf{X}(t), \mathbf{F}(t)] dt \quad (22)$$

The first term refers to the cost to the ends of the interval or to the boundary condition, while the second term refers to the cost to the entire

space. Depending on the requirements of the problem, functions $\theta(\mathbf{X}(t), t)$, $\phi(\mathbf{X}(t), \mathbf{F}(t))$ are taking specific forms. One of the most common forms of criterion J , which minimizes the energy of the system, is

$$J = \mathbf{X}(t_f)^T \mathbf{S} \mathbf{X}(t_f) + \int_{t_0}^{t_f} [\mathbf{X}(t)^T \mathbf{Q}(t) \mathbf{X}(t) + \mathbf{F}^T(t) \mathbf{R}(t) \mathbf{F}(t)] dt \quad (23)$$

The weighted matrixes $\mathbf{S}$, $\mathbf{Q}(t)$, and $\mathbf{R}(t)$ are selected according to the importance one wants to give to the error vector, $\mathbf{e}(t)$, or to the excitation vector $\mathbf{F}(t)$. The selection of suitable $\mathbf{S}$, $\mathbf{Q}(t)$, and $\mathbf{R}(t)$ for a particular problem is usually a difficult issue that requires experience and engineering insight.

The minimization of the cost criterion can be accomplished using the maximum principle introduced by Pontryagin and the principle of optimality introduced by Bellman. The procedure results in a system of differential equations as follows:

$$\begin{aligned} \dot{\mathbf{P}}(t) + \mathbf{P}(t)\mathbf{A}(t) + \mathbf{A}^T(t)\mathbf{P}(t) - \mathbf{P}(t)\mathbf{B}(t)\mathbf{R}^{-1}(t)\mathbf{B}^T(t) \\ \mathbf{P}(t) = -\mathbf{C}^T(t)\mathbf{Q}(t)\mathbf{C}(t) \\ \mathbf{P}(t_f) = -\mathbf{C}^T(t_f)\mathbf{Q}(t_f)\mathbf{C}(t_f) \end{aligned} \quad (24)$$

$$\begin{aligned} \dot{\boldsymbol{\mu}}(t) + [\mathbf{A}(t) - \mathbf{B}(t)\mathbf{R}^{-1}(t)\mathbf{B}^T(t)\mathbf{P}(t)]^T \\ \boldsymbol{\mu}(t) = -\mathbf{C}^T(t)\mathbf{Q}(t)\mathbf{X}^*(t) \\ \boldsymbol{\mu}(t_f) = -\mathbf{C}^T(t_f)\mathbf{Q}(t_f)\mathbf{X}^*(t_f) \end{aligned} \quad (25)$$

Solving the above differential equations, $\mathbf{P}(t)$ and $\boldsymbol{\mu}(t)$ are computed, and then from Eq. 26, the feedback matrix $\mathbf{K}(t)$ and the control force $\mathbf{F}(t)$ are calculated. Equation 24 is called Riccati equation:

$$\begin{aligned} \mathbf{f}(t) = \mathbf{K}(t)\mathbf{X}(t) + \boldsymbol{\rho}(t) \\ \mathbf{K}(t) = -\ddot{\mathbf{R}}^{-1}(t)\mathbf{B}^T(t)\mathbf{P}(t), \boldsymbol{\rho}(t) = \ddot{\mathbf{R}}^{-1}(t)\mathbf{B}^T(t)\boldsymbol{\mu}(t) \end{aligned} \quad (26)$$

The above control law is under the assumption that all states are available and measurable.

Actively and Semi-actively Controlled Structures Under Seismic Actions: Modeling and Analysis,

Fig. 10 The general flowchart of the pole placement control strategy

A

In civil structures it is unrealistic to expect that the state vector can be fully measured. The case that a few degrees of freedom are measured and used for the calculation of the control force is called output control, in contrast to the full-state control where all degrees of freedom of the system are measured. Suitable control design techniques, like observers with linear quadratic Gaussian (LQG) control, have been developed for output feedback and random disturbances. Many researchers have studied and applied optimal control in civil structures (Abdel-Rohman and Leipholz 1983; Chang and Soong 1980; Yang 1975). An evolutionary control of damaged systems using a rehabilitative, modified LQR algorithm has been proposed by Attard and Dansby (2008).

Pole Placement Algorithm

It should be noted that, if the external excitation is ignored or set to zero in the derivation of the Riccati equation, the provided control law is not optimal. In order to include the excitation in the Riccati equation, a priori knowledge of the loading history is required. This is generally not possible for excitations such as earthquakes, wind, or waves, which are common in structural engineering applications.

A control algorithm which addresses this difficulty is pole assignment (pole placement) algorithm. Pole placement algorithms have been studied extensively in the general control literature, while its applications in structural control have been investigated by Martin and Soong (1976), Leonard (1990), Soong (1990), Utku (1998), and Preumont (2002).

A procedure of on-line selection of poles in such a way that first resonance is avoided and secondly sufficient equivalent damping is added, based on the specific characteristics of the incoming dynamic earthquake excitation, have been proposed by Pnevmatikos and Gantes (2010a). This procedure drives the poles to their optimum location and does not need the poles to be predefined and constant during the application of dynamic loading. Numerical simulations show that sufficient reduction of the response, in terms of both displacement and acceleration, can be achieved for all examined earthquakes with reasonable amount of required equivalent control force. The procedure is shown schematically in Fig. 10. The effectiveness to the response of the structure of the control strategy is shown in Fig. 11. It is shown that both the displacement and the acceleration are reduced one order of magnitude.

Actively and Semi-actively Controlled Structures Under Seismic Actions: Modeling and Analysis,

Fig. 11 Displacement and acceleration of the controlled (*blue line*) and uncontrolled (*red line*) system for the third floor of the three-story building subjected to earthquake

H_2/H_∞ Control Algorithm

The objective of the H_2 or H_∞ control algorithms is to design a controller $\mathbf{K}$ that minimizes the H_2 or H_∞ norm of the closed-loop transfer function matrix, $\mathbf{H}$, from the disturbance to the output vector. By definition, the H_2 norm of a stable transfer function matrix is

$$\|\mathbf{H}\|_2 = \sqrt{\text{trace} \left\{ \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathbf{H}(j\omega) \mathbf{H}^*(j\omega) d\omega \right\}} \quad (27)$$

More details regarding the use of control H_2 and LQR methods for civil engineering applications can be found in Zacharenakis et al. (2001).

Sliding Mode Control

Sliding mode control or variable structure strategies were developed specifically for robust control of uncertain nonlinear systems. The fundamental idea of SMC is to design a controller to drive the state trajectory on the sliding surface (or switching surface), whereas the motion on the sliding surface is stable, remains there all the subsequent time, and moves toward the equilibrium position. The first step in SMC is to design the sliding surface on which the response is stable, while the second step is the determination of the control demand which will drive the response trajectory into the sliding surface and force it to stay there all the subsequent time. In most studies the sliding surface, $\mathbf{s}$, is defined as a linear combination of the state vector:

$$\mathbf{s} = \dot{\mathbf{U}} + \lambda \mathbf{U} = [\lambda \quad \mathbf{I}] \begin{bmatrix} \mathbf{U} \\ \dot{\mathbf{U}} \end{bmatrix} = \mathbf{P}\mathbf{X} \quad (28)$$

In the work of Slotin and Li (1991), a more general approach is proposed. The sliding surface can be obtained using optimal control theory. In the work of Pnevmatikos and Gantes (2009), the sliding surface, $\mathbf{s}$, is defined by pole assignment method, where the selection of the poles of the controlled system is based on the frequency content of the incoming earthquake signal.

Following the design of the sliding surface, the control force which will drive the response trajectory into this surface and force it to stay there is calculated using Lyapunov stability theory. To achieve this goal, first, a Lyapunov function is chosen, and then, under the condition that the derivative of the function $\mathbf{V}$ is negative, the control force is obtained. The control forces $\mathbf{F}$ are given by

$$\begin{aligned} \mathbf{F} &= \mathbf{G} - \delta \times \lambda^T, \mathbf{G} = -(\mathbf{P}\mathbf{B}_f)^{-1} \mathbf{P}(\mathbf{A}\mathbf{X} + \mathbf{B}_g \mathbf{a}_g), \\ \lambda &= \mathbf{s}^T \mathbf{P}\mathbf{B}_f \end{aligned} \quad (29)$$

Matrix $\mathbf{G}$ includes the restoring, damping, inertial, and seismic forces. The magnitude of $\mathbf{G}$

is very large for controlling conventional civil engineering structures. Thus, the control force should be restricted to a certain level, and a saturated controller should be considered in the design of SMC. In this case, full compensation of the response cannot be achieved. If the maximum control force is bounded by $\pm \mathbf{f}_{\max}$, the control force is estimated as follows:

$$\mathbf{F} = \begin{cases} \mathbf{G} - \delta \times \lambda^T, & \text{if } |\mathbf{G} - \delta \times \lambda^T| \leq \mathbf{f}_{\max} \\ \mathbf{f}_{\max} \text{sign}(\mathbf{G} - \delta \times \lambda^T), & \text{otherwise} \end{cases} \quad (30)$$

The force $\mathbf{f}_{\max}$ is specified by the device capacity.

Active Variable Stiffness Control Algorithm

Variable stiffness control has been developed by Kobori and verified experimentally at Kajima Research Institute in Japan, in 1993. The control algorithm is based on the nonresonant state under seismic excitation by altering the stiffness and thus natural frequencies, of a building, based on the nature of the earthquake. Nagarajaiah et al. (1998) developed a semi-active instantaneously variable stiffness (SAIVS) system which varies the structural stiffness continuously and smoothly so as to maintain a nonresonant state. Yang et al. (2000) have developed a resetting semi-active stiffness device (RSASD) and suitable algorithm to regulate RSASD at appropriate time instants.

In Pnevmatikos et al. (2004, 2010a), a control algorithm based on the frequency content of the incoming earthquake is described, suitable for application in active variable stiffness systems installed in buildings designed against seismic actions. The control strategy consists of two stages: (i) the design stage, where the bracing system is designed based on the frequency content of a range of earthquakes, and (ii) the operation phase, where the control algorithm uses the dynamic characteristics of the measured on-line excitation signal, in order to take an appropriate decision regarding the function of the variable stiffness device. Based on the frequency content

Actively and Semi-actively Controlled Structures Under Seismic Actions: Modeling and Analysis, Fig. 12 The integrated control strategy for buildings

equipped with active variable stiffness systems and subjected to earthquake actions

of the incoming signal, the variable stiffness device, by connecting or disconnecting the bracing system, alters the stiffness of the structure and consequently changes its dynamic characteristics in real time, avoiding resonance between the controlled structure and the applied signal. Thus, the structural safety and serviceability against extreme dynamic excitation are enhanced. The general scheme of the proposed algorithm is shown in Fig. 12.

Fuzzy Logic Control

A very useful application of fuzzy logic in civil engineering is fuzzy control. Fuzzy logic, introduced by Zadeh (1965), has to do with the way that the human brain deals with concepts such as uncertainty, vagueness, and imprecision. Boolean logic determines whether an argument definitely belongs or not to some set, while fuzzy logic considers the idea of partial truths, and determines the degree of membership of an argument to a fuzzy set.

Fuzzy control defines fuzzy rules to determine actions to be taken, based on the measured structure's responses. The advantages of fuzzy controller are simple algorithms, suitable for real-time control, no need for information on structural and vibration characteristics, and a robust system in terms of performance and implementation.

Fuzzy control uses experience instead of differential equations to determine desirable control actions. Fuzzy control consists of implementation of rules, in the format of IF...THEN statements, which relate the input variables to the control action. The process begins by first defining membership functions to classify the inputs and outputs using linguistic terms. In structural control applications, the inputs are usually a combination of structural responses: displacement, velocity, and acceleration. The input values are then converted to fuzzy values, using the membership functions. This step is referred to as fuzzification. The next step is

named decision making and consists of using predetermined rules to correlate the fuzzy inputs values to fuzzy outputs. Finally, in the last step, the fuzzy output values are defuzzified, that is, they are converted to values that can be used as control actions.

The rules and the membership functions are important to the effectiveness of the fuzzy controller. Several methods are available for the creation of such rules, including logical reasoning, experiments and simulations, and learning from examples. Fuzzy control rules can be created based on data obtained by an LQG controller. Genetic algorithms can be tuned to the membership functions in order to improve the results. Genetic algorithms can also be used to simultaneously determine the optimal rules and membership functions.

Fuzzy theory can be applied to determine the desired control force to be applied by the actuator. Neural network performance function selection can be used in structural control (Casciati et al. 1993).

Fuzzy logic has been used to vary the mechanical properties of the control device. It has been applied for the reduction of longitudinal bridge displacement due to earthquake or traffic loading with variable dampers or control of structural vibrations with hybrid systems composed of base isolation and semi-active dampers. Fuzzy control is also used to regulate a structure with an MR damper system (Choi Kang-Min et al. 2004, Zhou et al. 2003).

Clip Optimal Control

The clip optimal control has two parts: the first part consists of designing a control law assuming that an ideal device is installed to the building. In the second part, a controller is designed allowing the semi-active damper to develop the force that the control law calculated. In the first part, any control law can be chosen.

Clipped-optimal control strategy has been proposed by Dyke et al. (1996) to control a single MR damper. The control algorithm was extended to control multiple MR devices, and the performance of this algorithm has been experimentally verified.

In the clipped-optimal control algorithm, the control forces f_c is given by the following expression:

$$f_c = L^{-1} \left\{ -K_c(s) L \left\{ \begin{matrix} y_m \\ f_m \end{matrix} \right\} \right\} \quad (31)$$

where $L\{\}$ is the Laplace transform, $K_c(s)$ is a linear optimal controller obtained from H_2 or LQG strategies because of the stochastic nature of earthquake ground motions (any other control law can also be chosen), y_m is the measured structural response vector, and f_m is the measured control force vector.

Because the force generated in the semi-active device is dependent on the local responses of the structural system, the desired optimal control force, f_c , cannot always be produced by the control device. Only the control voltage, v_i , can be directly controlled to increase or decrease the force produced by the device. Thus, a force feedback loop is incorporated to induce the semi-active device to generate approximately the desired optimal control force f_c . To clip the active control law to the semi-active one and to generate approximately the desired optimal control force, the command signal is selected as follows.

When the semi-active device is providing the desired optimal force $f_i = f_c$, the voltage applied to the damper should remain at the present level. If the magnitude of the force produced by the device f_i is smaller than the magnitude of the required target force f_c and the two forces have the same sign, the voltage applied to the current driver is increased to the maximum level so as to increase the force produced by the device to match the desired control force. Otherwise, the commanded voltage is set to zero.

The above procedure that regulates the applied voltage has the following mathematical expression:

$$v_i = V_{\max} H((f_{ci} - f_i)f_i) \quad (32)$$

where $V_{\max}$ is the maximum voltage to the current driver and $H(\)$ is the Heaviside step function

which is a discontinuous function whose value is zero for negative argument and one for positive argument.

In clipped-optimal control algorithm, the command voltage takes two values, either zero or the maximum value. In some situations when the dominant frequencies of the system under control are low, large changes in the forces applied to the structure may result in high local acceleration values. This behavior is dependent on the time lag in the generation of the control voltage. In Yoshida (2003), a modification to the original clipped-optimal control algorithm is proposed to reduce this effect. In the modified version of the control algorithm, the control voltage can be any value between 0 and $V_{\max}$. The control voltage, v_{ci} , is determined using a linear relationship between the applied voltage and the maximum force of MR damper. The modified clipped-optimal control algorithm is given as

$$v_i = V_{ci}H((f_{ci} - f_i)f_i) \quad (33)$$

where

$$V_{ci} = \begin{cases} \mu f_{ci} & \text{for } f_{ci} \leq f_{\max} \\ V_{\max} & \text{for } f_{ci} > f_{\max} \end{cases} \quad (34)$$

Skyhook/Ground Hook Control

On skyhook control, the damper is controlled by two damping values. The choice between high or low state is made using the following law: based on the product of the relative velocity u_{rel} across the damper and the absolute velocity of the system body mass attached to that damper, a damping value is chosen as follows:

$$\begin{aligned} \dot{z}_b \times v_{rel} \geq 0 & \quad c = \text{high state} \\ \dot{z}_b \times v_{rel} \leq 0 & \quad c = \text{low state} \end{aligned} \quad (35)$$

The skyhook control is an on-off strategy. When the relative velocity of the damper is positive, the force of the damper acts to pull on the system body mass, while when the relative velocity of the damper is negative, the force of the damper pushes the body mass.

Since the damping values now are not limited to this state alone and can take any value within this state, a continuous version of skyhook control can be achieved. The choice of damping is now given as follows:

$$\begin{aligned} \dot{z}_b \times v_{rel} \geq 0 & \quad c = a \\ \dot{z}_b \times v_{rel} < 0 & \quad c = \text{low state} \end{aligned} \quad (36)$$

where

$$a = \max\{\text{low state}, \min(g \times \dot{z}_b, \text{high state})\} \quad (37)$$

In the case of ground hook control, the damper is adjusted to its high or low state depending on the product of the relative velocity across the damper and the absolute velocity of lower mass attached to that damper. Contrary to skyhook control, this control law is driving the lower vibration mass to a reduced vibration.

The mathematical expression of the ground hook control is as follows:

$$\begin{aligned} \dot{z}_t \times v_{rel} \leq 0 & \quad c = \text{high state} \\ \dot{z}_t \times v_{rel} > 0 & \quad c = \text{low state} \end{aligned} \quad (38)$$

The continuous ground hook control strategy is similar to the sky hook control.

Summary

Representative control devices and their applications have been presented. Then, mathematical formulations and simulation of controlled structures have been illustrated. Control algorithms suitable for civil structure inspired by the classical control theory were presented. Optimal control, LQR, pole assignment, sliding mode control, H_2 , fuzzy control, clipped-optimal control, and skyhook/ground hook control algorithms were briefly described. It was shown that with the help of modern technology, it is possible to control civil structures in order to protect them from earthquake excitations.

Introduction

Structural health monitoring using dynamic response measurement has received a tremendous attention over the last decades. A number of methods have been developed, including the novelty measure technique (Worden 1997), the GA-based substructural identification methods (Koh and Shankar 2003), and the evolutionary strategy (Franco et al. 2004). On the other hand, the Bayesian inference (Beck and Katafygiotis 1998; Beck 2010; Yuen 2010a) using probability logic provides a rigorous solution to parametric identification and uncertainty quantification for different problems in structural and geotechnical engineering, such as modal identification using nonstationary noisy response measurements (Yuen and Katafygiotis 2005; Yuen et al. 2006a), ambient vibration survey (Yuen and Katafygiotis 2006; Yuen et al. 2006b; Yuen and Kuok 2010a), particulate matters (Hoi et al. 2009), fatigue problem (Papadimitriou et al. 2011), and model class selection (Worden and Hensman 2012). A detailed review of Bayesian methods for structural dynamics and civil engineering can be found in Yuen and Kuok (2011). In particular, the well-known Kalman filter (KF) is one of the most widely applied recursive Bayesian state estimation techniques for trajectory estimation of linear dynamical systems (Kalman and Bucy 1961). Based on the concept of the KF, the extended Kalman filter (EKF) was developed for nonlinear systems (Jazwinski 1970). By introducing an augmented state vector, the EKF can be applied to parametric identification problems, and it has become a standard technique for state tracking, system identification, and control design for dynamical systems.

In the KF or EKF, the covariance matrices of the process noise and measurement noise are required. The conventional way is to tune these noise covariance matrices in a trial-and-error manner. However, ad hoc selection may lead to biased estimation, misleading uncertainty estimation, and even divergence problems (Zhou and Luecke 1994). Insights have been given into the convergence mechanisms, asymptotic

behavior, and estimation performance of the KF and EKF. It was emphasized that discrepancy between the actual and prescribed noise covariance matrices degrades substantially the performance of the filters and induces divergence problems. Existing methodologies for the estimation of these noise covariance matrices can be classified into three categories: covariance matching techniques (Myers and Tapley 1976), correlation techniques (Mehra 1970), and Bayesian techniques (Zhou and Luecke 1994). However, the majority of the literature focused on stationary situation which is not satisfied for general applications.

In this chapter, a computationally efficient Bayesian approach is presented for online estimation of the noise parameters. On the filter performance, it prevents the possible divergence problem and ensures the accuracy of the estimates and the estimated uncertainty. On the adaptability, it takes into explicit consideration the non-stationarity of the excitation, response, and measurement noise. These features of the presented approach enhance the applicability and reliability for the practical usage of the KF and EKF for online structural identification.

Next, the treatment of outliers in dynamic response data for online updating is addressed. In practice, it often occurs that some data points deviate drastically from the model output. The presence of outliers indicates irregularities of the data and/or deficiency of the model or theory. On one hand, outliers may occur due to extraordinarily large measurement error, e.g., human error, sensor noise, sensor failures, unknown environmental disturbances, etc. On the other hand, outliers may also occur due to imperfection of theory, i.e., existence of unmodeled mechanisms.

Since the performance of KF and EKF is severely deteriorated in the presence of outliers, a number of methods have been developed to enhance the robustness to outliers for KF and EKF. The first class of methods uses a non-Gaussian likelihood model for the measurement noise distribution and/or process noise distribution since the Gaussian likelihood model is sensitive to outliers, e.g., the Gaussian sum

approximation (Sorenson and Alspach 1971). However, this class of methods is often computationally very demanding, especially for online updating. Furthermore, the conditional mean of the state vector is not available in some cases. Another class of methods attempts to assign different weights, which are some heuristic function of the data, to different data points (Durovic and Kovacevic 1999). Methods of this class require tuning of the threshold parameters. However, performance is deteriorated with improper choice of the weights due to the difficulty in the choice of the thresholds. Therefore, this class of methods should be utilized with special attention.

In this chapter, an outlier-resistant extended Kalman filter (OR-EKF) is presented for robust online structural parametric identification using dynamic response data, contaminated with outliers in addition to Gaussian noise. In this algorithm, a novel outlier detection algorithm is embedded into the EKF. It is capable for robust online estimation of structural parameters using outlier-contaminated dynamic response data. Instead of definite judgment on the outlieriness of a data point, the OR-EKF provides its outlier probability, which is the extension of the concept in Yuen and Mu (2012). Data points with outlier probability over 0.5 will be regarded as suspicious data points, and they will be discarded for the identification purpose. In contrast to other existing outlier detection criteria that require some subjective threshold (e.g., normalized residual larger than 2.5), the outlier probability threshold of 0.5 is intuitive in the presented approach.

The third issue to be introduced is on the online model class selection. The usual approach in system identification is to find the best/optimal model in a prescribed class of models, e.g., class of shear building models with uncertain inter-story stiffnesses. This problem is commonly referred to as parametric identification. The more general problem of model class selection has not been explored as intensively as parametric identification. It is well known that a more complicated model class often fits the data better than one which has fewer adjustable parameters.

However, an over-fitted model leads to poor predictions because the model parameters depend too much on the detail of the data, and consequently the measurement noise and the modeling error play an important role in the data fitting. Therefore, in order to select a suitable model class for identification purposes, it is necessary to penalize a complicated model albeit the quantification of this penalty is a nontrivial task. This was first recognized by H. Jeffreys who did pioneering work on the application of Bayesian methods (Jeffreys 1961). In the present context, the selected class of models should agree closely with the observed behavior of the system but otherwise be as simple as possible. In recent years, the Bayesian approach to model class selection has been further developed by showing that the evidence for each model class provided by data automatically enforces a quantitative expression of principle of model parsimony or of Ockham's razor (Gull 1988). As a result, no ad hoc penalty is needed as in some of the earlier work on model class selection. Applications in civil engineering include the damage detection (Lam et al. 2006), selection of nonlinear hysteretic models (Muto and Beck 2008), soil compressibility (Yan et al. 2009), ambient effects to structural modal parameters (Yuen and Kuok 2010b), and seismic attenuation relationships (Yuen and Mu 2011). In this chapter, a recently developed recursive algorithm is introduced for Bayesian online model class selection.

In section “[Structural Parametric Identification by Extended Kalman Filter](#),” online structural parametric identification using the EKF will be briefly reviewed. In section “[Online Identification of Noise Parameters](#),” an online identification algorithm for the noise parameters in the EKF is introduced. Then, in section “[Outlier-Resistant Extended Kalman Filter](#),” an online outlier detection algorithm is presented, and it is embedded into the EKF. This algorithm allows for robust structural identification in the presence of possible outliers. In section “[Online Bayesian Model Class Selection](#),” a recursive Bayesian model class selection method is presented for non-parametric identification problems.

Structural Parametric Identification by Extended Kalman Filter

Formulation

Consider a linear dynamical system with N_d degrees of freedom (DOFs):

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{r}(\mathbf{x}, \dot{\mathbf{x}}; \boldsymbol{\varphi}) = \mathbf{T}\mathbf{f}(t) \quad (1)$$

where $\mathbf{M} \in \mathbb{R}^{N_d \times N_d}$ is the mass matrix of the system; $\mathbf{r}(\mathbf{x}, \dot{\mathbf{x}}; \boldsymbol{\varphi})$ is the restoring force that is governed by the unknown structural parameter vector $\boldsymbol{\varphi} \in \mathbb{R}^{N_\varphi}$ to be identified; $\mathbf{f}$ is the zero-mean Gaussian excitation; and $\mathbf{T} \in \mathbb{R}^{N_d \times N_f}$ is the force distribution matrix. The mass matrix $\mathbf{M}$ is assumed known.

Then, the augmented state vector $\mathbf{y}(t) \in \mathbb{R}^{2N_d + N_\varphi}$ is introduced to include the displacement, velocity, and the unknown structural parameters:

$$\mathbf{y}(t) = [\mathbf{x}^T, \dot{\mathbf{x}}^T, \boldsymbol{\varphi}^T]^T \quad (2)$$

where the superscript T denotes the transpose a vector/matrix. As a result, Eq. 1 can be converted to the state-space form:

$$\frac{d}{dt} \mathbf{y}(t) = \begin{bmatrix} -\mathbf{M}^{-1} \mathbf{r}(\mathbf{x}, \dot{\mathbf{x}}; \boldsymbol{\varphi}) \\ \mathbf{0}_{N_\varphi \times 1} \end{bmatrix} + \begin{bmatrix} \mathbf{0}_{N_d \times 1} \\ \mathbf{M}^{-1} \mathbf{T} \\ \mathbf{0}_{N_\varphi \times 1} \end{bmatrix} \mathbf{f}(t) \quad (3)$$

To simplify the notation, the rate vector and input distribution matrix are defined as follows:

$$\mathbf{s} \equiv \begin{bmatrix} -\mathbf{M}^{-1} \mathbf{r}(\mathbf{x}, \dot{\mathbf{x}}; \boldsymbol{\varphi}) \\ \mathbf{0}_{N_\varphi \times 1} \end{bmatrix}; \quad \mathbf{B} \equiv \begin{bmatrix} \mathbf{0}_{N_d \times N_f} \\ \mathbf{M}^{-1} \mathbf{T} \\ \mathbf{0}_{N_\varphi \times N_f} \end{bmatrix} \quad (4)$$

where $\mathbf{0}_{\alpha \times \beta}$ denotes the $\alpha \times \beta$ zero matrix.

The structural response is sampled at N_o DOFs with time step Δt , and the measurement at the k th time step can be represented by the observation vector:

$$\mathbf{z}_k = \mathbf{C}_d \mathbf{y}_k + \mathbf{n}_k \quad (5)$$

Where $\mathbf{y}_k \equiv \mathbf{y}(k\Delta t)$, $\mathbf{C}_d \in \mathbb{R}^{N_o \times (2N_d + N_\varphi)}$ is the observation matrix, and the measurement noise $\mathbf{n}_k$ is assumed to be Gaussian with zero-mean and covariance matrix $\sum \mathbf{n}_k \in \mathbb{R}^{N_o \times N_o}$. Note that the measurement noise $\mathbf{n}$ is assumed to be i.i.d. (independent and identically distributed) and statistically independent to the excitation $\mathbf{f}$.

In order to obtain a discrete state-space equation for computation, the functions in Eq. 4 is linearized for each time step $t \in [k\Delta t, (k+1)\Delta t)$ as follows:

$$\frac{d}{dt} \mathbf{y}(t) = \mathbf{s} \Big|_{\mathbf{y}(t)=\mathbf{y}_k} + \frac{\partial \mathbf{s}}{\partial \mathbf{y}} \Big|_{\mathbf{y}(t)=\mathbf{y}_k} (\mathbf{y}(t) - \mathbf{y}_k) + \mathbf{B}\mathbf{f}(t) \quad (6)$$

And it can be rearranged as follows:

$$\dot{\mathbf{y}}(t) = \mathbf{A}_k \mathbf{y}(t) + \mathbf{B}\mathbf{f}(t) + \mathbf{h}_k, \quad t \in [k\Delta t, (k+1)\Delta t] \quad (7)$$

where the system matrix $\mathbf{A}_k$ is given by

$$\mathbf{A}_k = \frac{\partial \mathbf{s}}{\partial \mathbf{y}} \Big|_{\mathbf{y}(t)=\mathbf{y}_k} = \begin{bmatrix} \mathbf{0}_{N_d \times N_d} & \mathbf{I}_{N_d} & \mathbf{0}_{N_d \times N_\varphi} \\ -\mathbf{M}^{-1} \frac{\partial \mathbf{r}}{\partial \mathbf{x}} & -\mathbf{M}^{-1} \frac{\partial \mathbf{r}}{\partial \dot{\mathbf{x}}} & -\mathbf{M}^{-1} \frac{\partial \mathbf{r}}{\partial \boldsymbol{\varphi}} \\ \mathbf{0}_{N_\varphi \times N_d} & \mathbf{0}_{N_\varphi \times N_d} & -\delta \mathbf{I}_{N_\varphi} \end{bmatrix} \quad (8)$$

and the vector $\mathbf{h}_k$ is given by

$$\mathbf{h}_k = \mathbf{r} \Big|_{\mathbf{y}(t)=\mathbf{y}_k} - \mathbf{A}_k \mathbf{y}_k \quad (9)$$

The variable δ in $\mathbf{A}_k$ in Eq. 8 is chosen as a small positive number to prevent singularity of the matrix $\mathbf{A}_k$; $\mathbf{I}_\alpha$, and $\mathbf{0}_{\alpha \times \beta}$ denote the $\alpha \times \alpha$ identity matrix and the $\alpha \times \beta$ zero matrix, respectively.

State Estimation and Parametric Identification by Kalman Filter

The augmented state vector $\mathbf{y}$ can be updated by the Kalman filter. First, the linearized state-space

equation in Eq. 7 can be discretized to a difference equation:

$$\mathbf{y}_{k+1} = \mathbf{A}_{d,k}\mathbf{y}_k + \mathbf{B}_{d,k}\mathbf{f}_k + \mathbf{h}_{d,k} \quad (10)$$

where $\mathbf{y}_{k+1} = \mathbf{y}((k+1)\Delta t)$, $\mathbf{A}_{d,k} = \exp(\mathbf{A}_k \Delta t)$, $\mathbf{B}_{d,k} = \mathbf{A}_k^{-1}(\mathbf{A}_{d,k} - \mathbf{I}_{2N_d+N_\varphi})\mathbf{B}$, $\mathbf{f}_k = \mathbf{f}(k\Delta t)$, and $\mathbf{h}_{d,k} = \mathbf{A}_k^{-1}(\mathbf{A}_{d,k} - \mathbf{I}_{2N_d+N_\varphi})\mathbf{h}_k$.

With the measurement $D_k \equiv \{\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_k\}$ defined in Eq. 5, the predicted state at the $(k+1)^{\text{th}}$ time step ($\mathbf{y}_{k+1|k} \equiv \mathbb{E}[\mathbf{y}_{k+1} | \mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_k]$) can be estimated by taking the conditional expected value of Eq. 10:

$$\mathbf{y}_{k+1|k} = \mathbf{A}_{d,k}\mathbf{y}_{k|k} + \mathbf{h}_{d,k} \quad (11)$$

where $\mathbf{y}_{k|k}$ is the updated state at the k th time step. In addition, the covariance matrix of $\mathbf{y}_{k+1|k}$ is

$$\Sigma_{\mathbf{y},k+1|k} = \mathbf{A}_{d,k}\Sigma_{\mathbf{y},k|k}\mathbf{A}_{d,k}^T + \mathbf{B}_{d,k}\Sigma_{\mathbf{f},k}\mathbf{B}_{d,k}^T \quad (12)$$

where $\Sigma_{\mathbf{f},k}$ is the covariance matrix of the excitation at the k th time step.

With a new data point $\mathbf{z}_{k+1}$, the updated state $\mathbf{y}_{k+1|k+1}$ and its covariance matrix $\Sigma_{\mathbf{y},k+1|k+1}$ can be obtained by using the following Kalman filter recursive formulae (Kalman and Bucy 1961):

$$\mathbf{y}_{k+1|k+1} = \mathbf{y}_{k+1|k} + \mathbf{G}_{k+1}(\mathbf{z}_{k+1} - \mathbf{C}_d\mathbf{y}_{k+1|k}) \quad (13)$$

$$\Sigma_{\mathbf{y},k+1|k+1} = (\mathbf{I}_{2N_d+N_\varphi} - \mathbf{G}_{k+1}\mathbf{C}_d)\Sigma_{\mathbf{y},k+1|k} \quad (14)$$

where $\mathbf{G}_{k+1}$ is called the Kalman filter gain (Kalman and Bucy 1961)

$$\mathbf{G}_{k+1} = \Sigma_{\mathbf{y},k+1|k}\mathbf{C}_d^T(\mathbf{C}_d\Sigma_{\mathbf{y},k+1|k}\mathbf{C}_d^T + \Sigma_{\mathbf{n},k})^{-1} \quad (15)$$

Fading Memory

Fading memory filtering was developed to compensate the modeling error in the identification

process (Sorensen and Sacks 1971). Here, it is employed to track the time-varying structural and noise parameters. The underlying concept of fading memory filtering is to discount the contribution of the past data gradually for adaptive identification of the time-varying parameters. This can be accomplished by assigning an appropriate weighting, which is called the fading factor $\mu(>1)$, to enlarge the estimated covariance matrix at every time step so that the information from the past data will fade out gradually. In particular, the covariance matrix of the filtered augmented state in Eq. 14 is modified as follows:

$$\Sigma_{\mathbf{y},k+1|k+1} = \mu(\mathbf{I}_{2N_d+N_\varphi} - \mathbf{G}_{k+1}\mathbf{C}_d)\Sigma_{\mathbf{y},k+1|k} \quad (16)$$

where μ is the widely adopted exponential fading factor (Sorensen and Sacks 1971)

$$\mu = \exp\left(\frac{\ln\mu_\sigma^2}{N_\mu}\right) \quad (17)$$

where $\mu \geq 1$. The effect of this exponential fading factor is to dilute the information of a data point with a factor of μ_σ^2 , in terms of the contribution to the posterior variance, after every N_μ time steps.

Online Identification of Noise Parameters

In this section, a Bayesian probabilistic approach is presented for online estimation of the noise parameters of the process noise and measurement noise. Section “[Parameterization and Bayesian Formulation](#)” introduces the parameterization of the noise covariance matrices and the Bayesian formulation. Thereafter, the online identification algorithm is presented in section “[Online Estimation of Noise Parameters](#).”

Parameterization and Bayesian Formulation

First, the covariance matrices of the process noise and measurement noise are parameterized

as $\Sigma_{f,k} = \Sigma_{f,k}(\theta_{f,k})$ and $\Sigma_{n,k+1} = \Sigma_{n,k+1}(\theta_{n,k+1})$, respectively. In other words, both matrices are time varying in order to allow online tracking. The uncertain noise parameter vector is given by

$$\theta_{k+1} = \left[\theta_{f,k}^T, \theta_{n,k+1}^T \right]^T \in \mathbb{R}^{N_\theta} \quad (18)$$

This parameterization allows for the tracking problem for general nonstationary situations. In the following, a concurrent procedure is introduced to estimate the noise parameter vector. As a result, not only the optimal estimation can be obtained but also the associated uncertainty can be quantified.

When a new measurement $\mathbf{z}_{k+1}$ is available, the noise parameters can be updated. Using the Bayes' theorem, the posterior probability density function (PDF) of the noise parameter vector given the measurement data set D_{k+1} is given by (Yuen 2010a)

$$p(\theta_{k+1}|D_{k+1}) = \frac{p(\theta_{k+1}|D_k)p(\mathbf{z}_{k+1}|\theta_{k+1}, D_k)}{p(\mathbf{z}_{k+1}|D_k)} \quad (19)$$

where $p(\theta_{k+1}|D_k)$ is the prior PDF of θ_{k+1} ; $p(\mathbf{z}_{k+1}|\theta_{k+1}, D_k)$ is the likelihood function; and $p(\mathbf{z}_{k+1}|D_k)$ is a normalizing constant such that the integral of the posterior PDF over the entire parameter space is unity. The prior PDF is approximated as a Gaussian distribution:

$$p(\theta_{k+1}|D_k) = (2\pi)^{-N_\theta/2} |\Sigma_{\theta,k+1|k}|^{-1/2} \exp \left[-\frac{1}{2} (\theta_{k+1} - \theta_{k+1|k})^T \Sigma_{\theta,k+1|k}^{-1} (\theta_{k+1} - \theta_{k+1|k}) \right] \quad (20)$$

Given the measurement D_k , the one-step ahead predictor for the noise parameters is taken as the updated noise parameters of the previous time step:

$$\theta_{k+1|k} = \theta_{k|k} \quad (21)$$

On the other hand, the associated covariance matrix is assumed to be the following:

$$\Sigma_{\theta,k+1|k} = \mu \Sigma_{\theta,k|k} \quad (22)$$

where the fading factor μ is defined in Eq. 17. Here, it is assumed that the noise covariances are time slowly varying so the ensemble mean can be approximately estimated by the temporal average with certain time delay.

On the other hand, the likelihood function is given by

$$p(\mathbf{z}_{k+1}|\theta_{k+1}, D_k) = (2\pi)^{-N_o/2} |\Sigma_{\mathbf{z},k+1|k}|^{-1/2} \exp \left[-\frac{1}{2} (\mathbf{z}_{k+1} - \mathbf{z}_{k+1|k})^T \Sigma_{\mathbf{z},k+1|k}^{-1} (\mathbf{z}_{k+1} - \mathbf{z}_{k+1|k}) \right] \quad (23)$$

where $\mathbf{z}_{k+1|k}$ and $\Sigma_{\mathbf{z},k+1|k}$ are readily obtained from Eqs. 11 and 12 given the measurement data set D_k :

$$\mathbf{z}_{k+1|k} = \mathbf{C}_d \mathbf{A}_{d,k} \mathbf{y}_{k|k} + \mathbf{C}_d \mathbf{h}_{d,k} \quad (24)$$

$$\Sigma_{\mathbf{z},k+1|k} = \mathbf{C}_d \mathbf{A}_{d,k} \Sigma_{\mathbf{y},k|k} \mathbf{A}_{d,k}^T \mathbf{C}_d^T + \mathbf{C}_d \mathbf{B}_{d,k} \Sigma_{f,k|k} \mathbf{B}_{d,k}^T \mathbf{C}_d^T + \Sigma_{n,k+1|k} \quad (25)$$

By substituting Eq. 20–Eq. 23 to Eq. 19, the posterior PDF becomes

$$p(\theta_{k+1}|D_{k+1}) = \frac{(2\pi)^{-(N_\theta+N_o)/2}}{p(\mathbf{z}_{k+1}|D_k) |\mu \Sigma_{\theta,k|k}|^{1/2}} |\Sigma_{\mathbf{z},k+1|k}|^{-1/2} \exp \left[-\frac{1}{2\mu} (\theta_{k+1} - \theta_{k|k})^T \Sigma_{\theta,k|k}^{-1} (\theta_{k+1} - \theta_{k|k}) - \frac{1}{2} (\mathbf{z}_{k+1} - \mathbf{z}_{k+1|k})^T \Sigma_{\mathbf{z},k+1|k}^{-1} (\mathbf{z}_{k+1} - \mathbf{z}_{k+1|k}) \right] \quad (26)$$

where $\mathbf{z}_{k+1|k}$ and $\Sigma_{\mathbf{z},k+1|k}$ are given by Eqs. 24 and 25, respectively. The objective function $J(\boldsymbol{\theta}_{k+1})$ is defined as the negative logarithm of

$$\begin{aligned} J(\boldsymbol{\theta}_{k+1}) = & \frac{1}{2} \ln |\Sigma_{\mathbf{z},k+1|k}| + \frac{1}{2\mu} (\boldsymbol{\theta}_{k+1} - \boldsymbol{\theta}_{k|k})^T \Sigma_{\boldsymbol{\theta},k|k}^{-1} (\boldsymbol{\theta}_{k+1} - \boldsymbol{\theta}_{k|k}) \\ & + \frac{1}{2} (\mathbf{z}_{k+1} - \mathbf{z}_{k+1|k})^T \Sigma_{\mathbf{z},k+1|k}^{-1} (\mathbf{z}_{k+1} - \mathbf{z}_{k+1|k}) \end{aligned} \quad (27)$$

The updated noise parameter vector $\boldsymbol{\theta}_{k+1|k+1}$ can be obtained by maximizing the posterior PDF $p(\boldsymbol{\theta}_{k+1}|D_{k+1})$ in Eq. 26, and it is equivalent to minimizing the objective function $J(\boldsymbol{\theta}_{k+1})$ in Eq. 27:

$$\boldsymbol{\theta}_{k+1|k+1} = \arg \min_{\boldsymbol{\theta}_{k+1}} J(\boldsymbol{\theta}_{k+1}) \quad (28)$$

Furthermore, the uncertainty of the updated noise parameter vector $\boldsymbol{\theta}_{k+1|k+1}$ can be represented by its covariance matrix $\Sigma_{\boldsymbol{\theta},k+1|k+1}$ which is equal to the inverse of the Hessian matrix of the objective function calculated at $\boldsymbol{\theta}_{k+1} = \boldsymbol{\theta}_{k+1|k+1}$:

$$\Sigma_{\boldsymbol{\theta},k+1|k+1} = [\mathbf{H}_J(\boldsymbol{\theta}_{k+1|k+1})]^{-1} \quad (29)$$

where the Hessian matrix is given by $\mathbf{H}_J(\boldsymbol{\theta}_{k+1|k+1}) = [\nabla^2 J(\boldsymbol{\theta}_{k+1})]_{\boldsymbol{\theta}_{k+1}=\boldsymbol{\theta}_{k+1|k+1}}$, and it can be computed using the finite difference method.

Online Estimation of Noise Parameters

In this subsection, a computationally efficient algorithm is presented for online updating of the noise parameter vector $\boldsymbol{\theta}_{k+1|k+1}$ and the associated covariance matrix $\Sigma_{\boldsymbol{\theta},k+1|k+1}$. Starting with an arbitrary initial condition $\boldsymbol{\theta}_{0|0}$ and arbitrarily positive definite matrix $\Sigma_{\boldsymbol{\theta},0|0}$, the noise parameter vector and its associated covariance matrix can be updated based on Eqs. 28 and 29. As aforementioned, the noise parameter vector can be updated by solving the optimization problem in Eq. 28. However, due to the large prior uncertainty and numerical considerations, a training process is necessary for a preliminary solution

the posterior PDF without taking the terms that do not depend on the noise parameters:

before solving directly this optimization problem. In this training process, a heuristic local search method is utilized. Thereafter, a modified Newton's method is used for the operating stage. Details of this estimation scheme are presented as follows.

Training Stage

At the beginning of the identification process, the Gaussian approximation is inaccurate due to the large prior uncertainty, i.e., large difference between the prior mean and the actual values, and large prior variances. Therefore, solving directly the optimization problem in Eq. 28 may result in computational problems. Herein, a training process is introduced to obtain a preliminary solution before the long-term operating stage. During the training process, a heuristic local search method is applied to the optimization problem. This method provides a generic tool for complicated optimization problems. The basic principle is to conduct the optimization within a prescribed parameter set. By exhaustive search from this finite set, the optimal (suboptimal) solution is the one that gives the smallest objective function value. Specifically, the candidate parameter set of the $(k+1)$ th time step is defined as

$$\begin{aligned} \Theta_{k+1} \equiv & \left\{ \boldsymbol{\theta}_{k+1} \in \mathbb{R}^{N_\theta} : \theta_{k+1}^{(l)} = v \theta_{k|k}^{(l)}, l = 1, \dots, \right. \\ & \left. N_\theta, v \in \{1/2, 1, 2\} \right\} \end{aligned} \quad (30)$$

where $\theta_{k+1}^{(l)}$ and $\theta_{k|k}^{(l)}$ are the l th component of the noise parameter vector $\boldsymbol{\theta}_{k+1}$ and the l th

component of the updated noise parameter vector $\theta_{k|k}$, respectively. By considering all the combinations of the N_θ noise parameters, there are 3^{N_θ} candidate solutions in the candidate parameter set Θ_{k+1} . The objective function $J(\theta_{k+1})$ is evaluated for all candidate solutions. Then, the noise parameter vector is updated under the optimization criterion given by

$$\theta_{k+1|k+1} = \arg \min_{\theta_{k+1}} J(\theta_{k+1}) \text{ where } \theta_{k+1} \in \Theta_{k+1} \quad (31)$$

This heuristic local search method is the online version of the half-or-double optimization method in Yuen et al. (2007). If the updated noise parameter vectors of ten consecutive time steps remain unchanged, the training process will be terminated. However, this training process is enforced to be not shorter than one fundamental period of the underlying dynamical system (or its equivalent linear system). This one-period requirement ensures that sufficient information can be gained from the data for the preliminary estimation of the augmented state vector.

Operating Stage

After the training process, the updated noise parameter vector is obtained using a modified Newton's method in the operating stage. Instead of an iterative procedure in the Newton's method, it is necessary to take only one step because the updated parameter vector of the previous time step is very close to the solution. Specifically, the updated noise parameter vector can be obtained as follows:

$$\theta_{k+1|k+1} = \theta_{k|k} - \Sigma_{\theta, k|k} \left(\nabla J(\theta_k) |_{\theta_k = \theta_{k|k}} \right) \quad (32)$$

where the gradient $\nabla J(\theta_k) |_{\theta_k = \theta_{k|k}}$ can be computed using the finite difference method. Since the information carried by one data point is limited, the updated noise parameter vector of the previous time step provides an accurate initial estimation of the current time step. Therefore, Eq. 32 is sufficient without iteration.

Outlier-Resistant Extended Kalman Filter

In this section, the outlier-resistant extended Kalman filter (OR-EKF) is introduced for online outlier detection and robust structural parametric identification using dynamic response data. In this algorithm, an online outlier detection algorithm is embedded into the EKF. Section “[Online Outlier Detection by Outlier Probability](#)” introduces the concept of outlier probability, and it will be utilized for online outlier detection. This outlier detection algorithm is embedded in the EKF for online structural identification. Section “[Procedure of the Outlier-Resistant Extended Kalman Filter](#)” summarizes the procedure of the OR-EKF algorithm.

Online Outlier Detection by Outlier Probability

In this section, the concept of outlier probability and an online outlier detection algorithm are introduced. Instead of definite judgment on the “outlierness” of a data point being an outlier, this algorithm provides the outlier probability, which is the extension of the concept in Yuen and Mu (2012) for linear regression problems, for the measurement in each time step. The outlier probability is a function of the normalized residual, which is defined as the difference between the measured value and the corresponding one-step-ahead predictor, normalized by its standard deviation. Data points with outlier probability over 0.5 are regarded as suspicious data points, and they will be discarded for the identification purpose.

Outlier Probability

Recall that the predicted state $\mathbf{y}_{k+1|k}$ can be calculated using Eq. 11. Therefore, the one-step-ahead predictor of the measurements is readily obtained:

$$\mathbf{z}_{k+1|k} = \mathbf{C}_d \mathbf{y}_{k+1|k} \quad (33)$$

Use $z_{k+1}^{(s)}$ to denote the s th component of the observation vector $\mathbf{z}_{k+1}$ and $z_{k+1|k}^{(s)}$, $s = 1, 2, \dots, N_o$, to denote the s th component of its

one-step-ahead predictor $\mathbf{z}_{k+1|k}$. Hereafter, the superscript (s) is used to denote the sth component of a vector. Then, the normalized residual (prediction error) for $\mathbf{z}_{k+1}^{(s)}$ can be defined (Myers and Tapley 1976):

$$\varepsilon_{k+1}^{(s)} = \left(z_{k+1}^{(s)} - \mathbf{z}_{k+1|k}^{(s)} \right) / \sigma_{\varepsilon, k+1}^{(s)} \quad (34)$$

where $\sigma_{\varepsilon, k+1}^{(s)}$ is the standard deviation for the sth measured channel of the difference between the measurement and the corresponding one-step-ahead predictor. Since the probability model for the measurement noise is Gaussian, the probability of a data point falling outside the interval $(-|\varepsilon_{k+1}^{(s)}|, |\varepsilon_{k+1}^{(s)}|)$ is

$$Q_{k+1} = 2\Phi\left(-\left|\varepsilon_{k+1}^{(s)}\right|\right) \quad (35)$$

where $\Phi(\cdot)$ is the cumulative distribution function (CDF) of the standard Gaussian random variable. Then, a moving time window is introduced to include not more than N_w previous regular data points, and the set $\mathbf{R}_k^{(s)}$ is introduced to include the absolute normalized residuals of the regular data points in this time window:

$$\mathbf{R}_k^{(s)} = \left\{ \left| \varepsilon_l^{(s)} \right| : z_l^{(s)} \text{ is a regular data point, } l = \max(1, k - N_w), \dots, k \right\} \quad (36)$$

where $n(\mathbf{R}_k^{(s)})$ is used to denote the number of elements in the set $\mathbf{R}_k^{(s)}$. Define η_{k+1} as the number of elements, among the set $\mathbf{R}_k^{(s)}$, with absolute normalized residuals larger than $|\varepsilon_{k+1}^{(s)}|$. In other words, η_{k+1} is the number of previous regular data points, within the aforementioned moving time window, that has larger absolute normalized residual than the current one. This is equivalent to counting the numbers of the normalized residuals of the previous regular points falling outside the interval $(-|\varepsilon_{k+1}^{(s)}|, |\varepsilon_{k+1}^{(s)}|)$ in the moving time window.

In order to determine the outlierness of a data point $\mathbf{z}_{k+1}^{(s)}$, the probability that τ points, out of $n(\mathbf{R}_k^{(s)}) + 1$ data points, falling outside the interval $(-|\varepsilon_{k+1}^{(s)}|, |\varepsilon_{k+1}^{(s)}|)$ is considered. Note that τ is a random variable, and it follows the binomial

distribution with probability Q_{k+1} . Then, the outlier probability for $\mathbf{z}_{k+1}^{(s)}$ can be defined as the probability that no more than η_{k+1} samples drawn from the normalized residuals among the $(\mathbf{R}_k^{(s)})$ previous regular data points fall outside the interval $(-|\varepsilon_{k+1}^{(s)}|, |\varepsilon_{k+1}^{(s)}|)$. This probability can be obtained by considering the total probability:

$$P_o\left(\mathbf{z}_{k+1}^{(s)}\right) = \sum_{\tau=0}^{\eta_{k+1}} C\left(n\left(\mathbf{R}_k^{(s)}\right), \tau\right) Q_{k+1}^{\tau} \left(1 - Q_{k+1}\right)^{n\left(\mathbf{R}_k^{(s)}\right) - \tau} \quad (37)$$

where $C\left(n\left(\mathbf{R}_k^{(s)}\right), \tau\right) = \frac{n\left(\mathbf{R}_k^{(s)}\right)!}{\left(n\left(\mathbf{R}_k^{(s)}\right) - \tau\right)! \tau!}$ is the

binomial coefficient. Note that introduction of this moving window is to release the memory and computational burden in considering the entire history. On the other hand, due to possible condition changes of the excitation and the underlying structure, it is suitable to consider only the past data points in a reasonable neighborhood of the current time step. It is suggested to use a value for N_w that corresponds to approximately 100 fundamental periods of the structure.

Efficient Screening Criteria

In order to enhance the computational efficiency, an efficient screening rule is introduced. First, a data point is classified as a regular point when $|\varepsilon_{k+1}^{(s)}| \leq \xi_L$, a conservatively small bound (e.g., $\xi_L = 2$). On the other hand, a data point is classified as an outlier when $|\varepsilon_{k+1}^{(s)}| \geq \xi_U$. This bound can be obtained by solving $[1 - 2\Phi(-\xi_U)]^{N_w+1} = 0.5$. As a result, it is given by

$$\xi_U = -\Phi^{-1}\left[\left(\frac{1}{2} - 2^{-\frac{1}{N_w+1}}\right)\right] \quad (38)$$

where Φ^{-1} is the quantile function which is the inverse function of the CDF of the standard Gaussian random variable. For example, $\xi_U = 3.9787$ for $N_w = 10,000$. It can be easily shown that the outlier probability of the data points with absolute normalized residuals larger than ξ_U is larger than 0.5. Therefore, computation of the outlier probability is necessary only when

the absolute value of the normalized residual of the measurement lies within (ξ_L, ξ_U) . This helps to determine efficiently the outlierlikeness for a large portion of data points without computing the outlier probability.

Procedure of the Outlier-Resistant Extended Kalman Filter

The procedure of the OR-EKF is summarized as follows.

Training Process

The initial value of $\sigma_{e,1}^{(s)}$ can be estimated as follows:

- (i) Implement the EKF for roughly ten fundamental periods of the underlying system.
- (ii) Calculate the residuals $|z_k^{(s)} - z_{k|k-1}^{(s)}|$ for these data points (ignoring the first one period of data points), and sort them in the ascending order. Then, the standard deviation $\sigma_{e,1}^{(s)}$ can be estimated as the value of the 68-percentile point. This is a robust estimator of the standard deviation for possible presence of outliers.

Operating Process

Compute the ξ_U using Eq. 38 and initialize $R_0^{(s)} = \phi$, an empty set for $s = 1, \dots, N_o$.

1. Calculate the one-step-ahead predictor $\mathbf{z}_{k+1|k}$ by Eq. 33, the s th element of the normalized residual $|e_{k+1}^{(s)}|$ by Eq. 34.
2.
 - (a) If $|e_{k+1}^{(s)}| \leq \xi_L$ ($=2$), $z_{k+1}^{(s)}$ will be classified as a regular data point.
 - (b) If $|e_{k+1}^{(s)}| \geq \xi_U$, $z_{k+1}^{(s)}$ will be classified as an outlier.
 - (c) When $\xi_L < |e_{k+1}^{(s)}| < \xi_U$, calculate Q_{k+1} using Eq. 35 and count η_{k+1} from $R_k^{(s)}$. Then, compute the outlier probability $P_o(z_{k+1}^{(s)})$ using Eq. 37. If $P_o(z_{k+1}^{(s)}) < 0.5$, $z_{k+1}^{(s)}$ will be classified as a regular point. Otherwise, it will be concluded as a suspicious data point, and it will be discarded for identification purpose.
3. According to the outlier detection result in step (2), update the sets $R_{k+1}^{(s)}$, $s = 1, \dots, N_o$. If $z_{k+1}^{(s)}$ is an outlier, $R_{k+1}^{(s)} = R_k^{(s)}$.

If $z_{k+1}^{(s)}$ is a regular point, $R_{k+1}^{(s)} = R_k^{(s)} \cup \{|e_{k+1}^{(s)}|\}$ if $n(R_k^{(s)}) < N_w$. Otherwise, $R_{k+1}^{(s)} = R_k^{(s)} \cup \{|e_{k+1}^{(s)}|\} - \{|e_{old}^{(s)}|\}$, where $|e_{old}^{(s)}|$ is the oldest element in the set $R_k^{(s)}$.

4. Update $\sigma_{e,k+2}^{(s)}$ with the elements in $R_{k+1}^{(s)}$. This can be done by using recursive formula.
5. Remove the outliers from $\mathbf{z}_{k+1}$. Note that the observation matrix $\mathbf{C}_d$ and the noise covariance matrix $\Sigma_{n,k+1}$ have to be modified accordingly.
6. Update the state vector and the associated covariance matrix using the measurement obtained from step (5) using Eq. 13 to Eq. 15. If all N_0 elements of the $(k+1)$ th data points are suspicious measurements, $\mathbf{y}_{k+1|k+1} = \mathbf{y}_{k+1|k}$ and $\Sigma_{y,k+1|k+1} = \Sigma_{y,k+1|k}$.
7. Continue for the next time step.

One can refer to Mu and Yuen (2014) for numerical examples.

Online Bayesian Model Class Selection

Bayesian model class selection is utilized for selecting the most plausible model class from a set of N_C dynamic model class candidates $C_1, C_2, \dots, C_{N_C}$ by considering their plausibility $P(C_j|D)$ conditional on the available set of dynamic measurement D (Beck and Yuen 2004; Yuen 2010b):

$$P(C_j|D) = \frac{P(C_j)p(D|C_j)}{p(D)} \quad (39)$$

where the denominator $p(D)$ is the normalizing constant; $P(C_j)$ is the prior plausibility of model class C_j . In general, a noninformative prior can be used, i.e., $P(C_j) = 1/N_C$, where $j = 1, \dots, N_C$, and $p(D|C_j)$ is the evidence given by

$$p(D|C_j) = \int_{\Theta_j} p(D|\boldsymbol{\theta}; C_j) p(\boldsymbol{\theta}|C_j) d\boldsymbol{\theta} \quad (40)$$

where Θ_j denotes the parameter space of model class C_j . However, direct numerical computation of this integral is in general computationally

prohibitive unless the number of uncertain parameters is very small (say 3 or less). To overcome this computational obstacle, an asymptotic expansion was developed for the globally identifiable cases (Beck and Yuen 2004):

$$p(D|C_j) \approx (2\pi)^{N_j/2} p(D|\hat{\boldsymbol{\theta}}; C_j) p(\hat{\boldsymbol{\theta}}|C_j) \left| \mathbf{H}_j(\hat{\boldsymbol{\theta}}) \right|^{-1/2} \quad (41)$$

where N_j is the number of uncertain parameters of model class C_j and $\hat{\boldsymbol{\theta}}$ is the parameter vector that maximizes the posterior PDF, which is proportional to the integrand on the right-hand side of Eq. 40.

In the locally identifiable cases (Katafygiotis and Beck 1998), the product of the likelihood function and the prior PDF can be approximately by weighted Gaussian distributions:

$$p(D|\boldsymbol{\theta}; C_j) p(\boldsymbol{\theta}|C_j) \approx (2\pi)^{N_j/2} \sum_{i=1}^{N_i} p(D|\hat{\boldsymbol{\theta}}_i; C_j) p(\hat{\boldsymbol{\theta}}_i|C_j) \left| \mathbf{H}_j(\hat{\boldsymbol{\theta}}_i) \right|^{-1/2} G\left(\boldsymbol{\theta}; \hat{\boldsymbol{\theta}}, \mathbf{H}_j(\hat{\boldsymbol{\theta}}_i)^{-1}\right) \quad (42)$$

where $\hat{\boldsymbol{\theta}}_i$ is the i th local optimal point, $i = 1, \dots, N_i$, and $G\left(\boldsymbol{\theta}; \hat{\boldsymbol{\theta}}_i, \mathbf{H}_j(\hat{\boldsymbol{\theta}}_i)^{-1}\right)$ denotes the multivariate Gaussian distribution for the random vector $\boldsymbol{\theta}$ with mean $\hat{\boldsymbol{\theta}}_i$ and covariance matrix $\mathbf{H}_j(\hat{\boldsymbol{\theta}}_i)^{-1}$. Then, the evidence is given as

$$p(D|C_j) \approx (2\pi)^{N_j/2} \sum_{i=1}^{N_i} p(D|\hat{\boldsymbol{\theta}}_i; C_j) p(\hat{\boldsymbol{\theta}}_i|C_j) \left| \mathbf{H}_j(\hat{\boldsymbol{\theta}}_i) \right|^{-1/2} \quad (43)$$

For general unidentifiable cases, the evidence integral in Eq. 40 can be computed using the transitional Markov chain Monte Carlo (TMCMC) method (Ching and Chen 2007).

Next, an online Bayesian model class selection algorithm is introduced. It was first developed to model the transportation system of particulate matters (Hoi et al. 2011). The plausibility of model class C_j conditional on the measured data up to the $(k+1)$ th time step $D_{k+1} = \{\mathbf{z}_1, \dots, \mathbf{z}_{k+1}\}$ can be rewritten into the following form using the Bayes' theorem:

$$P(C_j|D_{k+1}) = \frac{p(\mathbf{z}_{k+1}|D_k; C_j) P(C_j|D_k)}{p(\mathbf{z}_{k+1}|D_k)} \quad (44)$$

where $p(\mathbf{z}_{k+1}|D_k; C_j)$ denotes the evidence of model class C_j conditional on the data of the

previous k time steps. The denominator $p(\mathbf{z}_{k+1}|D_k)$ is a normalizing constant that does not depend on the model class. Note that the plausibility $P(C_j|D_0)$ is deduced to the prior plausibility of the model class $P(C_j)$. By using the theorem of total probability, the conditional evidence $p(\mathbf{z}_{k+1}|D_k; C_j)$ can be expressed as

$$p(\mathbf{z}_{k+1}|D_k; C_j) = \int_{\Theta_j} p(\mathbf{z}_{k+1}|\boldsymbol{\theta}_k; D_k; C_j) p(\boldsymbol{\theta}_k|D_k; C_j) d\boldsymbol{\theta}_k \quad (45)$$

where $\boldsymbol{\theta}_k$ denotes the parameter vector containing all the uncertain parameters of model class C_j at the k th time step and Θ_j denotes the parameter space for model class C_j . The factor $p(\mathbf{z}_{k+1}|\boldsymbol{\theta}_k; D_k; C_j)$ in the integrand is the conditional likelihood function of model class C_j at the $(k+1)$ th time step. It represents the level of data fitting of the model with a given parameter vector $\boldsymbol{\theta}_k$. The second factor in the integrand is the posterior PDF of the parameter vector $\boldsymbol{\theta}_k$ conditional on the previous data points $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_k$. For globally identifiable cases, an asymptotic expansion of this integral can be obtained in a similar fashion as Eq. 41:

$$p(\mathbf{z}_{k+1}|D_k; C_j) \approx (2\pi)^{N_j/2} p(\mathbf{z}_{k+1}|\boldsymbol{\theta}_k^*; D_k; C_j) p(\boldsymbol{\theta}_k^*|D_k; C_j) \left| \mathbf{H}_j(\boldsymbol{\theta}_k^*) \right|^{-1/2} \quad (46)$$

where N_j denotes the number of uncertain parameters in model class C_j and $\boldsymbol{\theta}_k^* = \boldsymbol{\theta}_{k|k+1}$ is the parameter vector that maximizes the integrand of

Eq. 45 but it will be approximated by $\boldsymbol{\theta}_k^* \approx \boldsymbol{\theta}_{k|k}$. The maximum conditional likelihood of model class C_j evaluated at $\boldsymbol{\theta}_{k|k}$ is given by

$$\begin{aligned} p(\mathbf{z}_{k+1}|\boldsymbol{\theta}_k^*; D_k; C_j) &\approx (2\pi)^{-N_o/2} |\mathbf{C}_d \boldsymbol{\Sigma}_{\mathbf{y}, k+1|k} \mathbf{C}_d^T + \boldsymbol{\Sigma}_{\mathbf{n}, k+1}|^{-1/2} \\ &\times \exp \left[-\frac{1}{2} \left(\mathbf{z}_{k+1} - \mathbf{C}_d \mathbf{y}_{k+1|k} \right)^T (\mathbf{C}_d \boldsymbol{\Sigma}_{\mathbf{y}, k+1|k} \mathbf{C}_d^T + \boldsymbol{\Sigma}_{\mathbf{n}, k+1})^{-1} \left(\mathbf{z}_{k+1} - \mathbf{C}_d \mathbf{y}_{k+1|k} \right) \right] \end{aligned} \quad (47)$$

The maximum posterior probability density of $\boldsymbol{\theta}_k^*$ conditional on D_k for model class C_j is given by

$$p(\boldsymbol{\theta}_k^*|D_k; C_j) \approx (2\pi)^{-N_j/2} |\boldsymbol{\Sigma}_{\boldsymbol{\theta}, k|k}|^{-1/2} \quad (48)$$

where $\boldsymbol{\Sigma}_{\boldsymbol{\theta}, k|k}$ denotes the covariance matrix of the updated parameters. The matrix $\mathbf{H}_j(\boldsymbol{\theta}_k^*)$ denotes the Hessian matrix of the negative natural logarithm of the integrand in Eq. 45 with respect to the parameter vector, evaluated at $\boldsymbol{\theta}_k^*$:

$$\begin{aligned} \mathbf{H}_j(\boldsymbol{\theta}_k^*) &= -[\nabla \ln p(\mathbf{z}_{k+1}|\boldsymbol{\theta}_k; D_k; C_j) \nabla^T] |_{\boldsymbol{\theta}_k = \boldsymbol{\theta}_{k|k}} \\ &+ \sum_{\boldsymbol{\theta}_{k|k}}^{-1} \end{aligned} \quad (49)$$

where ∇ denotes the gradient operator with respect to the parameter vector $\boldsymbol{\theta}_k$. The term $[\nabla \ln p(\mathbf{z}_{k+1}|\boldsymbol{\theta}_k; D_k; C_j) \nabla^T] |_{\boldsymbol{\theta}_k = \boldsymbol{\theta}_{k|k}}$ can be calculated using the finite difference method. Therefore, the conditional evidence in Eq. 46 can be calculated using Eq. 47–49.

the state vector, the structural parameters and their associated uncertainty. This approach allows for the tracking of nonstationary process noise and measurement noise. It estimates the noise parameters recursively for every time step. Then, the outlier-resistant extended Kalman filter (OR-EKF) was presented for robust online outlier detection and structural parametric identification. This method embeds an online outlier detection algorithm into the EKF. It is capable for robust estimation of structural parameters using outlier-contaminated dynamic response data in an online manner. In contrast to other existing robust KF/EKF algorithms, the OR-EKF requires no prior information of the outlier distribution model. Finally, the Bayesian model class selection approach allows for nonparametric online structural identification. This recursive algorithm allows for online model class selection to maintain the optimal balance between the data fitting capability and the robustness to modeling error and measurement noise. Through these recent developments, it is expected that reliable online structural identification using EKF can be achieved.

Summary

This chapter presented several recent advances in online structural identification using the extended Kalman filter (EKF). First, a Bayesian approach was introduced for online identification of the noise parameters. This approach resolves the divergence problem possibly encountered in the conventional EKF due to improper selection of the noise covariance matrices. Furthermore, the presented approach ensures reliable estimation of

Operational modal analysis; Operational modal testing

Introduction

Ambient vibration testing (AVT), long-term dynamic monitoring, and operational modal analysis (OMA, i.e., the identification of modal parameters from ambient vibration data) of Cultural Heritage structures are a rather recent topic, and only a limited number of complete investigations are reported in the literature (Jaishi et al. 2003; Bennati et al. 2005; Ivorra and Pallares 2006; Gentile and Saisi 2007, 2013; Pau and Vestroni 2008; Casarin and Modena 2008; Peña et al. 2010; Ramos et al. 2010; Aras et al. 2011; Oliveira et al. 2012). On the other hand, there is a growing interest on this topic since the preservation of Cultural Heritage is of primary concern in many countries all over the world.

AVT and OMA are especially suitable to historic structures for several reasons: (a) the easy and fully nondestructive way of testing, performed by measuring only the structural response under ambient excitation; (b) the sustainability of testing, which does not interfere with the normal use of the structure and does not induce additional loads rather than those due

to normal conditions (dead loads, wind, micro-tremors); and (c) the multiple-input nature of ambient excitation, ensuring that the response includes the contribution of a certain number of modes. It is indeed true that the response of a historic building to ambient excitation is generally low, but this cannot be considered a prohibitive issue as currently highly sensitive and relatively inexpensive accelerometers are available on the market.

In addition, the popularity of operational modal testing and analysis of civil engineering structures has been favored also by the technological advances (i.e., the availability of data acquisition and storage systems, which are fully computer based) and by the large number of output-only modal identification techniques available in the literature (see, e.g., Magalhães and Cunha 2011).

Furthermore, AVT and OMA seem ideal tools to methodologically complement the investigations currently carried out to assess the structural safety of Cultural Heritage structures. Although general rules, which can be applied to all historic constructions, are very difficult to define, it is generally agreed (see, e.g., Binda et al. 2000) that the first phase of a correct diagnostic approach (i.e., the evaluation of the current health state or performance of the building) involves the collection of all the essential information on the geometry of the building, its evolution from the origin to the present state, the construction technologies, the characteristics of masonry texture, the mechanical characterization of the materials, and the evaluation of their state of preservation.

The above documentary and experimental information – as it is suggested also in current Italian Guidelines for the seismic risk mitigation of Cultural Heritage (DPCM 2011) – provide a 1st-level diagnosis, highlighting the overall state of preservation, the presence of local defects and vulnerabilities, as well as the need of possible repair interventions, especially when local issues are detected; in this case, the intervention design should be addressed by simplified local models (see, e.g., Giuffrè 1993; DPCM 2011).

In principle, the previously collected knowledge of the building should be synthesized in

a finite element (FE) model of the structure. The FE model, in turn, should provide a 2nd-level diagnosis since it could be used for evaluating the structural safety under service loads, predicting the performance under exceptional loads (such as earthquakes), and simulating the effects of structural modifications or repair interventions.

However, FE modeling of historic structures is characterized by well-known issues:

- (a) The correlation between the results of local tests (which indeed provide the mechanical characterization of the materials) and quantitative parameters to build up global structural capacity models is still an open issue (Binda et al. 2000).
- (b) The structural model of a historic structure, even when all the collected information is accurately represented, continues to involve significant uncertainties, e.g., in the material properties (and their distribution) as well as in the boundary conditions. This aspect is especially critical for complex historic buildings evolved in different phases.
- (c) FE models are often used, even in refined nonlinear analyses, without experimental validation, and only occasionally the model validation is roughly performed by using few available local data (such as the stress level evaluated in few points through flat-jack tests).

Within this context, one possible key role of AVT and OMA is to provide effective and accurate validation of the FE model prior to its use in numerical analysis, as demonstrated in different studies on temples and monuments (Jaishi et al. 2003; Pau and Vestroni 2008), churches (Casarin and Modena 2008; Ramos et al. 2010; Gattulli et al. 2013), ancient palaces (Aras et al. 2011), towers, and minarets (Bennati et al. 2005; Ivorra and Pallares 2006; Gentile and Saisi 2007, 2013; Peña et al. 2010; Ramos et al. 2010; Oliveira et al. 2012).

In some cases, AVT can possibly help also to limit the number of on-site and laboratory tests, which are time-consuming and cost-ineffective.

Other possible applications of ambient vibration-based modal analysis in the field of historic structures include periodic or continuous monitoring in order to evaluate the effects of repair interventions or to perform dynamics-based damage assessment (Ramos et al. 2010).

The present entry, after a review of some output-only modal identification techniques, presents the application of ambient vibration-based modal and structural identification to a historic masonry tower. Subsequently, the role of AVT and OMA in the preservation of Cultural Heritage structures is exemplified in a further application (i.e., the long-term dynamic monitoring of a tower) aimed at (1) evaluating the effects of structural modifications, (2) assessing the influence of environmental effects on natural frequencies, (3) identifying the evolution of damage mechanisms.

Modal Identification from Ambient Vibration Data

As previously pointed out, a large number of output-only modal identification techniques are available in the literature, ranging from the simple *peak picking* technique (PP, Bendat and Piersol 1993) to the more advanced *frequency domain decomposition* (FDD, Brincker et al. 2000) and *stochastic subspace identification* (SSI, van Overschee and De Moor 1996). In this section, the PP, FDD, and SSI techniques are briefly described.

Peak Picking and Frequency Domain Decomposition

The PP and FDD techniques work in frequency domain and are based on the evaluation of the spectral matrix $\mathbf{G}_{yy}(f)$ of the recorded responses:

$$\mathbf{G}_{yy}(f) = \mathbf{E} [\mathbf{Y}(f) \mathbf{Y}^H(f)] \quad (1)$$

where the vector $\mathbf{Y}(f)$ collects the responses in the frequency domain, the superscript H denotes the Hermitian transpose operation (i.e., complex conjugate matrix transpose), and $\mathbf{E}$ denotes expected value. The diagonal terms of the matrix $\mathbf{G}_{yy}(f)$ are the (real valued) auto-spectral

densities (ASD), while the other terms are the (complex) cross-spectral densities (CSD). The spectral matrix $\mathbf{G}_{yy}(f)$ is generally computed by using the modified periodogram method (Welch 1967). According to this approach, an average is made over each recorded signal, divided into M frames of $2n$ samples, where windowing and overlapping are applied.

The principle of the two techniques is easiest illustrated by recalling that any response vector $\mathbf{y}(t)$ can be expressed in modal coordinates $\mathbf{q}(t)$ as

$$\mathbf{y}(t) = \boldsymbol{\phi}_1 q_1(t) + \boldsymbol{\phi}_2 q_2(t) + \dots = \boldsymbol{\Phi} \mathbf{q}(t) \quad (2)$$

where $\boldsymbol{\phi}_i$ represents the i -th mode shape vector and $\boldsymbol{\Phi}$ is the mode shape matrix. Hence, the correlation matrix $\mathbf{C}_{yy}(\tau)$ (see, e.g., Bendat and Piersol 1993) of the responses

$$\mathbf{C}_{yy}(\tau) = \mathbb{E}[\mathbf{y}(t + \tau) \mathbf{y}^T(t)] \quad (3)$$

becomes

$$\mathbf{C}_{yy}(\tau) = \boldsymbol{\Phi} \mathbb{E}[\mathbf{q}(t + \tau) \mathbf{q}^T(t)] \boldsymbol{\Phi}^T = \boldsymbol{\Phi} \mathbf{C}_{qq}(\tau) \boldsymbol{\Phi}^T \quad (4)$$

On the other hand, the spectral matrix may be defined as the Fourier transform of the correlation matrix:

$$\mathbf{G}_{yy}(f) = \mathcal{F}[\mathbf{C}_{yy}(\tau)] = \boldsymbol{\Phi} \mathbf{G}_{qq}(f) \boldsymbol{\Phi}^H \quad (5)$$

where $\mathbf{G}_{qq}(f)$ is the spectral matrix of the modal coordinates. It is worth underlining that since the modal coordinates are uncorrelated, the matrix $\mathbf{G}_{qq}(f)$ is diagonal.

The more traditional approach to estimate the modal parameters of a structure is often called *peak picking* method after its key step: the identification of the resonant frequencies as the peaks of ASDs and CSDs. In fact, for a lightly damped structure subjected to a white-noise random excitation, both ASDs and CSDs reach a local maximum at the frequencies corresponding to the system normal modes (Bendat and Piersol 1993); furthermore, if the assumption is introduced of modes having well-separated frequencies, it can be shown (see, e.g., Peeters 2000) that

the spectral matrix can be approximated, in the neighborhood of a resonant frequency f_k , as

$$\mathbf{G}_{yy}(f_k) \approx \alpha_k \boldsymbol{\phi}_k \boldsymbol{\phi}_k^H \quad (6)$$

where α_k depends on the damping ratio, the natural frequency, the modal participation factor, and the excitation spectra. Equation 6 highlights that (a) each row or column of the spectral matrix at a natural frequency f_k can be considered as an estimate of the mode shape $\boldsymbol{\phi}_k$ at that frequency and (b) the square root of the diagonal terms of the spectral matrix at a natural frequency f_k can be considered as an estimate of the mode shape $\boldsymbol{\phi}_k$ at that frequency.

The PP technique leads to reliable results provided that the basic assumptions of low damping and well-separated modes are satisfied; drawbacks of the method are related to the difficulties in identifying closely spaced modes and damping ratios.

Some refinements or variants of the classic PP technique have been proposed in the literature. For example, Felber (1993) suggested obtaining a “global picture” of the eigenfrequencies by evaluating an appropriate function, called averaged normalized power spectral density (ANPSD). More specifically, only the diagonal elements of the spectral matrix $\mathbf{G}_{yy}(f)$ are considered, normalized, and averaged so that a unique function is obtained, summarizing the information on the “modal” peaks contained in all the ASDs.

The FDD technique (Brincker et al. 2000) involves the singular value decomposition (SVD) of the spectral matrix at each frequency and the inspection of the curves representing the singular values, in order to identify the resonant frequencies and to estimate the corresponding mode shape using the information contained in the singular vectors of the SVD.

The SVD of the spectral matrix at each frequency is given by

$$\mathbf{G}_{yy}(f) = \mathbf{U}(f) \boldsymbol{\Sigma}(f) \mathbf{U}^H(f) \quad (7)$$

where the diagonal matrix $\boldsymbol{\Sigma}$ collects the real positive singular values in descending order and $\mathbf{U}$ is a complex matrix containing the singular

vectors as columns. The SVD is used for estimating the rank of $\mathbf{G}_{yy}$ at each frequency with the number of nonzero singular values being equal to the rank; if only one mode is important at a given frequency f_k , as it has to be expected for well-separated modes, the spectral matrix can be approximated by a rank-one matrix:

$$\mathbf{G}_{yy}(f) \approx \mathbf{u}_1(f)\sigma_1(f)\mathbf{u}_1^H(f) \quad (8)$$

By comparing Eq. 5 with Eq. 7, it is evident that (if the mode shapes are orthogonal) Eq. 5 is an SVD of the spectral matrix. Furthermore, the comparison of Eqs. 6 and 8 clearly reveals that the first singular vector $\mathbf{u}_1(f)$ is an estimate of the mode shape. Since the first singular value $\sigma_1(f)$ at each frequency represents the strength of the dominating vibration mode at that frequency, the first singular function can be suitably used as a modal indication function (yielding the resonant frequencies as local maxima). In addition, the successive singular values contain either noise or modes close to a strong dominating one.

The FDD is a rather simple procedure that represents an improvement of the PP because:

1. The SVD is an effective method for separating signal space from noise space, and the evaluation of mode shapes is automatic and significantly easier than in the PP.
2. The FDD technique is able to detect closely spaced modes. In such instances, more than one singular value will reach a maximum in the neighborhood of a given frequency, and every singular vector corresponding to a nonzero singular value is a mode shape estimate. The latter, however, is valid in the strict sense for orthogonal modes.
3. The damping ratios can be identified through the refinement of the FDD technique, namely, the *enhanced frequency domain decomposition* (EFDD, Brincker et al. 2001). The EFDD technique is based on the fact that the first singular value in the neighborhood of a resonant peak is the ASD of a modal coordinate. Hence, moving the partially identified ASD of the modal coordinate back in the time

domain by inverse FFT yields a free decaying time domain function, which represents the autocorrelation function of the modal coordinate. The natural frequency and the related damping ratio are thus simply found by estimating crossing times and employing the logarithmic decrement method.

Stochastic Subspace Identification

The SSI technique lies in the class of time domain methods and is based on the discrete-time stochastic state-space form of the dynamics of a linear time-invariant system under unknown excitation.

The continuous-time state-space equation of motion of a linear time-invariant system can be written as

$$\dot{x}(t) = \mathbf{A}_c x(t) + \mathbf{B}_c f(t) \quad (9)$$

$$\mathbf{A}_c = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C}_1 \end{bmatrix} \quad \mathbf{B}_c = \begin{bmatrix} \mathbf{0} \\ \mathbf{M}^{-1} \end{bmatrix} \quad (10)$$

where

- $x(t) = [\mathbf{u}(t)^T \quad \dot{\mathbf{u}}(t)^T]^T \in \mathfrak{R}^{2N \times 2N}$ is the state vector of the process, containing the displacement $\mathbf{u}(t)$ and the velocity $\dot{\mathbf{u}}(t)$ vectors.
- $\mathbf{A}_c \in \mathfrak{R}^{2N \times 2N}$ is the continuous-time state matrix, which is related to the matrices of mass $\mathbf{M}$, damping $\mathbf{C}_1$, and stiffness $\mathbf{K}$.
- $f(t) \in \mathfrak{R}^N$ is the load vector and $\mathbf{B}_c \in \mathfrak{R}^{2N \times N}$ is the system control influence coefficient matrix.
- The subscript c denotes continuous time.

It should be noticed that the eigenvalues Λ_c and eigenvectors Ψ of the state-space matrix $\mathbf{A}_c$ (solving the eigenvalue problem $\mathbf{A}_c \Psi = \Psi \Lambda_c$) contain the eigenvalues and the eigenvectors of the original second-order system $\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}_1\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = f(t)$.

In dynamic testing, only a subset L of the N responses are measured; hence, the vector of measured outputs $\mathbf{y}(t) \in \mathfrak{R}^L$ can be expressed as

$$\mathbf{y}(t) = \mathbf{C}_a \ddot{\mathbf{u}}(t) + \mathbf{C}_v \dot{\mathbf{u}}(t) + \mathbf{C}_d \mathbf{u}(t) \quad (11)$$

where $\mathbf{C}_a$, $\mathbf{C}_v$, and $\mathbf{C}_d$ are the output location matrices for accelerations, velocity, and displacements, respectively. These matrices contain a lot of zeros and a few unit entries since they are formulated in order to assign the measured degrees of freedom. The vector $\mathbf{y}(t)$ can be written as

$$\mathbf{y}(t) = \mathbf{C}_c \mathbf{x}(t) + \mathbf{D}_c \mathbf{f}(t) \quad (12)$$

$$\begin{aligned} \mathbf{C}_c &= [\mathbf{C}_d - \mathbf{C}_a \mathbf{M}^{-1} \mathbf{K}, \quad \mathbf{C}_v - \mathbf{C}_a \mathbf{M}^{-1} \mathbf{C}_1] \\ \mathbf{D}_c &= \mathbf{C}_a \mathbf{M}^{-1} \end{aligned} \quad (13)$$

By combining the state Eq. 9 and the observation Eq. 12, the classical continuous-time state-space model is found:

$$\begin{cases} \dot{\mathbf{x}}(t) = \mathbf{A}_c \mathbf{x}(t) + \mathbf{B}_c \mathbf{f}(t) \\ \mathbf{y}(t) = \mathbf{C}_c \mathbf{x}(t) + \mathbf{D}_c \mathbf{f}(t) \end{cases} \quad (14)$$

Since real measurements are taken at discrete-time instants and in order to fit model Eq. 14 to the measurements, this model needs to be converted into discrete time. Hence, assuming a constant sampling period Δt and that the input is piecewise constant over the sampling period, the continuous-time equations (Eq. 14) are discretized and solved at all discrete-time instants $t_k = k\Delta t$, obtaining the discrete-time state-space model:

$$\begin{cases} \mathbf{x}_{k+1} = \mathbf{A} \mathbf{x}_k + \mathbf{B} \mathbf{f}_k \\ \mathbf{y}_k = \mathbf{C} \mathbf{x}_k + \mathbf{D} \mathbf{f}_k \end{cases} \quad (15)$$

where $\mathbf{x}_k$ is the discrete-time state vector (containing displacements and velocities describing the state of the system at time instant $t_k = k\Delta t$), $\mathbf{f}_k$ and $\mathbf{y}_k$ are the sampled input and output vectors, $\mathbf{A}$ is the discrete state matrix (dependent on the mass, stiffness, and damping properties of the structure), $\mathbf{B}$ is the discrete input matrix, $\mathbf{C}$ is the discrete output matrix (which maps the state vector into the measured output), and $\mathbf{D}$ is the direct transmission matrix. The matrices $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, and $\mathbf{D}$ are related to their continuous-time counterparts Eq. 10 and Eq. 13 by the following:

$$\begin{aligned} \mathbf{A} &= e^{\mathbf{A}_c \Delta t} & \mathbf{B} &= (\mathbf{A} - \mathbf{I}) \mathbf{A}_c^{-1} \mathbf{B}_c \\ \mathbf{C} &= \mathbf{C}_c & \mathbf{E} &= \mathbf{E}_c \end{aligned} \quad (16)$$

It is finally observed that the deterministic model (Eq. 15) is not capable of exactly describing real measurement data; consequently, Eq. 15 needs to be modified to account for both the process noise $\mathbf{w}_k \in \mathfrak{R}^{2N}$ due to disturbances and modeling inaccuracies and the measurement noise $\mathbf{v}_k \in \mathfrak{R}^L$ due to sensor inaccuracy:

$$\begin{cases} \mathbf{x}_{k+1} = \mathbf{A} \mathbf{x}_k + \mathbf{B} \mathbf{f}_k + \mathbf{w}_k \\ \mathbf{y}_k = \mathbf{C} \mathbf{x}_k + \mathbf{D} \mathbf{f}_k + \mathbf{v}_k \end{cases} \quad (17)$$

Furthermore, both $\mathbf{w}_k$ and $\mathbf{v}_k$ are unmeasurable vectors, assumed to be zero mean, white, and with covariance matrices:

$$\mathbb{E} \left[\begin{pmatrix} \mathbf{w}_p \\ \mathbf{v}_p \end{pmatrix} \begin{pmatrix} \mathbf{w}_p^T & \mathbf{v}_p^T \end{pmatrix} \right] = \begin{bmatrix} \mathbf{Q} & \mathbf{S} \\ \mathbf{S}^T & \mathbf{R} \end{bmatrix} \delta_{pq} \quad (18)$$

It is very important to remark that an AVT provides information only on the vibration responses of a structure excited by unmeasured inputs. Consequently, it is impossible to distinguish the input term $\mathbf{f}_k$ from the noise terms $\mathbf{w}_k$ and $\mathbf{v}_k$ in Eq. 17. This results in the following discrete-time stochastic state-space model:

$$\begin{cases} \mathbf{x}_{k+1} = \mathbf{A} \mathbf{x}_k + \mathbf{w}_k \\ \mathbf{y}_k = \mathbf{C} \mathbf{x}_k + \mathbf{v}_k \end{cases} \quad (19)$$

where the input is implicitly modeled by the noise terms and the white noise assumption of these terms turns out to be essential: if the white noise assumption is violated because the input contains some dominant frequency components, these frequency components cannot be distinguished from the eigenfrequencies of the system (of the state matrix $\mathbf{A}$).

The key step of the SSI techniques is the estimation of the state-space matrices $\mathbf{A}$ and $\mathbf{C}$ from the measured output $\mathbf{y}_k$. The estimation of $\mathbf{A}$ and $\mathbf{C}$ can be performed by using different algorithms. The well-known data-driven SSI algorithms are based on linear algebra theorems

(van Overschee and De Moor 1996) demonstrating that the state-space matrices can be calculated from the knowledge of the block Hankel matrix of the measurements, defined as

$$\mathbf{H}_i = \begin{pmatrix} \mathbf{y}_0 & \mathbf{y}_1 & \cdots & \mathbf{y}_{j-1} \\ \mathbf{y}_1 & \mathbf{y}_2 & \cdots & \mathbf{y}_j \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{y}_{i-1} & \mathbf{y}_i & \cdots & \mathbf{y}_{i+j-2} \\ \hline \mathbf{y}_i & \mathbf{y}_{i+1} & \cdots & \mathbf{y}_{i+j-1} \\ \mathbf{y}_{i+1} & \mathbf{y}_{i+2} & \cdots & \mathbf{y}_{i+j} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{y}_{2i-1} & \mathbf{y}_{2i} & \cdots & \mathbf{y}_{2i+j-2} \end{pmatrix} = \begin{pmatrix} \mathbf{Y}_p \\ \mathbf{Y}_f \end{pmatrix} \quad (20)$$

where $2i$ and j are user-defined quantities, representing the number of output block rows and the number of columns of matrix $\mathbf{H}_i$, respectively.

In Eq. 2, the block Hankel matrix of the measurements is subdivided into two sub-matrices, named as $\mathbf{Y}_p$ and $\mathbf{Y}_f$, which are usually referred to as past and future output block matrices. The orthogonal projection of the row space of $\mathbf{Y}_f$ onto the row space of $\mathbf{Y}_p$ can be directly calculated yielding to matrix $\mathbf{P}_i$, which is known as projection matrix. The observability matrix $\mathbf{O}_i$ of the system – which, in turn, allows to compute $\mathbf{A}$ and $\mathbf{C}$ – can be estimated from the SVD of matrix $\mathbf{W}_1 \mathbf{P}_i \mathbf{W}_2$, where $\mathbf{W}_1$ and $\mathbf{W}_2$ are convenient weight matrices. The available SSI-data algorithms essentially differ for the expressions of the weight matrices (van Overschee and De Moor 1996).

After estimating the model matrices, the modal parameters f_i , ζ_i , and ϕ_i of the structural system are calculated from

$$\mathbf{A} = \mathbf{\Psi} \mathbf{\Lambda} \mathbf{\Psi}^{-1} \quad (21a)$$

$$\mathbf{\Lambda} = \text{diag}(\lambda_i) \quad \lambda_i^c = \frac{\ln \lambda_i}{\Delta t} \quad (21b)$$

$$f_i = \frac{|\lambda_i^c|}{2\pi} \quad \zeta_i = \frac{\text{real}(\lambda_i^c)}{|\lambda_i^c|} \quad (21c)$$

$$\mathbf{\Phi} = [\phi_1, \phi_2, \dots, \phi_i, \dots] = \mathbf{C} \mathbf{\Psi} \quad (21d)$$

It is further noticed that the order $2N$ of the model should equal, in principle, twice the

number of modes that are needed to accurately describe the structural response. However, with the purpose of detecting weakly excited modes, it is often necessary to consider more than $2N$ values, which are what would be physically sufficient. On the other hand, over-modeling leads to the appearance of spurious modes associated with the noise content of the measurements. A common practice for identifying the physical modes is based on the creation of the stabilization diagrams, where the modal parameters obtained for increasing model orders are collectively represented. A physical mode is conceivably identified when consistent frequencies, damping, and mode shapes (classified as stable poles) are obtained for models of increasing order.

Ambient Vibration Testing and Structural Identification of a Historic Masonry Tower

Description of the Tower

The first investigated historic building is a bell tower (Fig. 1), about 37.0 m high and built in stonework masonry (Gentile and Saisi 2013). The tower – located in the small town of Arcisate (northern Italy) – has a square cross section, with sides of 5.8 m, and is connected to the church *Chiesa Collegiata* on the East side and partly on the South side. The church, dedicated to St. Vittore, dates back to the fifteenth century and replaced a more ancient church, built in the fourth century and modified in the eleventh century. Probably the tower foundation dates back to the late Roman age, as well.

The first historic document concerning the tower goes back to the sixteenth century and reports St. Carlo Borromeo's request of access modification. Seven orders of floors are present, with five of them being defined by masonry offsets at the corners and by corresponding sequences of small hanging arches marking the floor levels; the last two orders were probably added in the eighteenth century to host the bell trusses. The wall thickness decreases

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 1 (a) View of the bell tower of *Chiesa Collegiata* (Arcisate, Varese); (b) crack patterns on the fronts of the tower (dimensions in m)

progressively along the height, from 135 cm at the ground level up to 65 cm at the top level.

Although extensive visual inspections and few sonic tests generally indicate that the stone masonry is relatively compact and of fairly good execution, the masonry texture appears locally often highly disordered and characterized by the local presence of vertical joints.

The crack pattern (Fig. 1b) has been accurately surveyed also by using an aerial platform. The tower exhibits long vertical cracks on every side, most of them cutting the entire wall thickness and passing through the keystones of the arch window openings. These cracks are mainly distributed between the second/third order of the tower. Many superficial cracks are also diffused, particularly on the North and West fronts, which are not adjacent to the church.

The visual inspection highlighted that the upper part of the tower, beneath the belfry level, could be probably considered the most vulnerable, due to the widespread mortar erosion and the infilled openings (Fig. 1b), mainly on the East and North fronts; in addition, the infillings are often not properly linked to the surrounding load-bearing masonry.

Ambient Vibration Testing Procedures and Modal Identification

The dynamic tests were carried out in June 2007, using a 16-channel data acquisition system and WR 731A piezoelectric accelerometers (10 V/g sensitivity and 0.5 g peak acceleration). Each accelerometer was connected with a short cable (1 m) to a WR P31 power unit/amplifier, providing the constant current needed to power the accelerometer's internal amplifier, signal amplification, and selective filtering.

The response of the tower was measured in 15 selected points, belonging to 5 different cross sections along the height of the building, according to the sensor layout illustrated in Fig. 2a. Figure 2b shows the mounting of accelerometers in the instrumented cross section at level +22.78 m.

The acceleration time histories induced by ambient excitation were recorded for 3,600 s at a sampling frequency of 200 Hz. A sample of the acceleration time histories recorded during the test in the upper part of the tower is shown in Fig. 3: it should be noticed that very low level of ambient excitation was present during the tests, with the maximum recorded acceleration being always lower than 0.4 cm/s^2 .

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 2 (a) Sensor layout adopted in the dynamic tests (dimensions in m), (b) mounting of the accelerometers at level +22.78 m

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 4 (a) First singular value (SV) curve and identification of natural frequencies (*FDD*), (b) stabilization diagram and automatic (*A*) identification of natural frequencies (*SSI*)

The modal identification was performed using time windows of 3,600 s, in order to comply with the widely agreed recommendation of using an appropriate duration of the acquired time window (ranging between 1,000 and 2,000 times the fundamental period of the structure; see, e.g., Cantieni 2005) to obtain accurate estimates of the modal parameters from OMA techniques. In fact, as already pointed out in section “[Modal Identification from Ambient Vibration Data](#),” OMA methods assume that the excitation input is a zero mean Gaussian white noise, and this assumption is as closely verified as the length of the acquired time window is longer.

The extraction of modal parameters from ambient vibration data was carried out using the FDD and the data-driven SSI techniques available in the commercial software ARTEMIS (SVS 2012). Notwithstanding the very low level of ambient response (Fig. 3) that existed during the tests, the application of both techniques allowed to identify five vibration modes in the frequency range of 0–6 Hz.

The results of OMA in terms of natural frequencies can be summarized through the plots of Fig. 4a, b, showing the first singular value (SV) of the spectral matrix and the stabilization diagrams obtained by applying the FDD and the SSI technique, respectively. The inspection of Fig. 4a highlights that the FDD technique provides a clear indication of the tower modes through well-defined local maxima in the first SV; similarly, Fig. 4b shows that the alignments of the stable poles in the stabilization diagram of the SSI method provide a clear indication of these modes, as well. Furthermore, Fig. 4a, b shows the correspondence of the natural frequency estimates between the two techniques, with the resonant peaks of Fig. 4a being placed practically at the same frequencies of the alignments of stable poles in Fig. 4b.

As it had to be expected, the identified modes can be classified as bending and torsion. Figure 5 shows the identified mode shapes (SSI technique): dominant bending (B) modes were identified at 1.22 (B1), 1.28 (B2), 4.01 (B3), and

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 5 Vibration modes identified from ambient vibration data (SSI)

4.16 Hz (B4), while only one torsion mode (T1) was identified at 3.60 Hz. It is observed that the dominant bending modes of the tower involve flexure practically along the diagonals.

FE Modeling and Model Tuning

A 3D structural model (Fig. 6) of the tower was developed (using the FE program Straus7), based on the available geometric survey.

The tower was modeled using 8-node brick elements. A relatively large number of finite elements have been used in the model, so that a regular distribution of masses could be obtained, and all the geometric variations and openings in the load-bearing walls could be reasonably represented. The model consists of 3,475 solid elements with 17,052 active degrees of freedom.

Since the geometry of the tower was surveyed on site and accurately described in the model, the main uncertainties are related to the characteristics of the material and boundary conditions. In order to reduce the number of uncertainties in the model calibration, the following initial assumptions were introduced: (a) homogeneous distribution of the masonry elastic properties; (b) the weight per unit volume of the masonry and Poisson's ratio of the masonry were assumed as 17.0 kN/m³ and 0.15, respectively; and (c) the tower footing was considered as fixed since the soil-structure interaction is hardly

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 6 Finite element model of the tower

involved at the low level of ambient vibrations that existed during the tests.

Under the above assumptions, a sensitivity analysis (see, e.g., Maia and Silva 1997) pointed out that sensitive parameters were (1) the average Young's modulus E of stone masonry, since all natural frequencies are very sensitive to its variation; (2) the ratio $\alpha = G/E$, implying the assumption of orthotropic material and significantly affecting the natural frequency of the torsion mode; (3) the connection between the tower and the neighboring building (represented by linear nodal springs), which highly affects the bending mode shapes.

Ambient Vibration Testing of Cultural Heritage Structures,
Fig. 7 Vibration modes of the initial model

Hence, three steps of manual tuning were carried out to establish a base FE model. In the base model, the following assumptions were adopted:

1. An orthotropic elastic behavior was assumed for the stone masonry, with the average characteristics of the material being $E = 3.00$ GPa and $G_{13} = G_{23} = 0.45$ GPa (corresponding to $\alpha = G_{13}/E = G_{23}/E = 0.15$). It is worth noting that the assumed Young's modulus was in good agreement with the results of the tests performed to characterize the masonry and reported in (Binda et al. 2012): more specifically, the average sonic velocity (P waves) varied between 1,620 and 2,240 m/s², and the values measured by double flat-jack tests at the base of the tower were slightly larger than 3.00 GPa.
2. The effects of the connection between the tower and the church were accounted for through a series of linear (nodal) springs of constant k . After tuning the parameter k in a preselected interval (1×10^4 kN/m $\leq k \leq 10 \times 10^4$ kN/m), the value $k = 4 \times 10^4$ kN/m was assumed since it tends to minimize the average difference between the measured and predicted modal frequencies.

Figure 7 illustrates the dynamic characteristics of the base model and highlights that the mode shapes are fully consistent with the experimental results (Fig. 5). Furthermore, the correspondence with the identified frequencies is fairly good for

the first three modes. The discrepancy is conceivably related to the simplified distribution of the model elastic properties.

As suggested by the mode shapes, the higher bending modes depend on the elastic characteristics of the masonry in the upper part of the tower. In addition, as pointed out in section “[Description of the Tower](#),” the upper region is characterized by a more evident mortar joint erosion and changes of the masonry texture including wide infilled openings on the East and North fronts, beneath the belfry level.

Hence, the distribution of Young's modulus was updated, and the tower was divided in two regions, with the masonry Young's modulus being assumed as constant within each zone. The two regions, denoted as I and II, correspond to the lower five levels of the building (E_I , $h \leq 26.0$ m, including a large number of passing-through cracks) and the upper part (E_{II} , $h > 26.0$ m, including infilled/repared areas and the belfry), respectively. The possible set of updating parameters includes E_I , E_{II} , α , and k . It should be noticed that assuming only one parameter α means that the ratio between the shear moduli in the two regions of the tower equals to the ratio between Young's moduli.

Subsequently, the optimal values of the updating structural parameters were determined. Among the different classes of procedures available in the literature (see, e.g., Friswell and Mottershead 1995), it was decided to evaluate the updating parameters by minimizing the

Ambient Vibration Testing of Cultural Heritage Structures, Table 1 Structural parameters for FE model identification

Structural parameter	Base value	Upper value	Base value	Optimal value
E_I (height ≤ 26 m) (GPa)	2.0	4.0	3.0	2.97
E_{II} (height > 26 m) (GPa)	1.0	3.0	2.0	1.60
α	0.110	0.190	0.150	0.172
k (kN/m)	1.0×10^4	10.0×10^4	4.0×10^4	8.30×10^4

difference between theoretical and experimental natural frequencies, through the simple procedure proposed in (Douglas and Reid 1982). According to this approach, the dependence of the natural frequencies of the model on the unknown structural parameters X_k ($k = I, 2, \dots, N$) is approximated around the current values of X_k , by the following:

$$f_i^*(X_1, X_2, \dots, X_N) = \sum_{k=1}^N [A_{i,k}X_k + B_{i,k}X_k^2] + C_i \quad (22)$$

where f_i^* represents the approximation of the i -th frequency of the FE model. Once the set of approximating functions Eq. 22 has been established, the structural parameters of the model are evaluated by a least-square minimization of the difference between each f_i^* and its experimental counterpart f_i^{EXP} :

$$J = \sum_{i=1}^M w_i \varepsilon_i^2 \quad (23a)$$

$$\varepsilon_i = f_i^{\text{EXP}} - f_i^*(X_1, X_2, \dots, X_N) \quad (23b)$$

where w_i is a weight constant. However, Eq. 22 represents a reasonable approximation in a range, around the “base” value of the structural parameters X_k^B , limited by lower X_k^L and upper values X_k^U ($k = I, 2, \dots, N$); thus, the coefficients A_{ik} , B_{ik} , C_i are dependent on both the base value of the structural parameters and the range in which these parameters can vary. The coefficients A_{ik} , B_{ik} , C_i are readily evaluated from $(2N + I)$ finite element analyses (Douglas and Reid 1982), each with a different choice of the parameters: the first choice of the parameters corresponds to the base

values; then each parameter is varied, one at time, from the base value to upper and lower limit, respectively.

It is further noticed that, in principle, the quadratic approximation Eq. 22 is as better as the base values are closer to the solution; hence, the accuracy and stability of the optimal estimates should be carefully checked either by the complete correlation with the experimental data or by repeating the procedure with new base values.

Table 1 summarizes the optimal estimates of the structural parameters, the base values, and the assumed lower and upper limits. By examining the optimal values in Table 1, the following comments can be made: (a) the optimal values of the elastic parameters in the lower region ($E_I = 2.97$ GPa, $G_{13}^I = G_{23}^I = \alpha \times E_I = 0.172 \times 2.97 \cong 0.51$ GPa) are very similar to those of the base model; (b) the optimal estimates of the elastic parameters in the upper region ($E_{II} = 1.60$ GPa, $G_{13}^{II} = G_{23}^{II} = \alpha \times E_{II} = 0.172 \times 1.60 \cong 0.28$ GPa) turned out to be lower than the ones in the lower part, reflecting the observed state of preservation in that region; and (c) the stiffness of the springs becomes larger than in the base model to better fit the ratio between the natural frequencies of the first two modes.

Figure 8 shows the mode shapes of the updated model, corresponding to the experimental ones (Fig. 5), and the correlation with the measured modal behavior. It should be noticed that the updated model represents an excellent approximation of the real structure, with the maximum relative error between predicted and measured modal frequencies being larger than 1 % only for mode B3.

Furthermore, also the correlation between mode shapes – estimated via the MAC (Allemang and Brown 1983) – is very good for

Ambient Vibration Testing of Cultural Heritage Structures,

Fig. 8 Vibration modes of the optimal (updated) model

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 9 Views of the *Gabbia Tower* (Mantua, Italy) from South and East

the first two modes (with the MAC being larger than 0.96); for the higher modes, the MAC is in the range 0.711–0.845 so that appreciable average differences are detected and again related to the simplified distribution of the model elastic properties, which were held constant for large regions of the tower.

Ambient Vibration Testing and Dynamic Monitoring of a Historic Masonry Tower

After the Italian earthquakes of May 2012, an extensive research program has been performed to assess the state of preservation of the tallest historic tower in Mantua, Italy. The investigated tower (Fig. 9), about 54.0 m high and dating back to the twelfth century, is known as the *Gabbia Tower*.

Visual inspection of all main-bearing walls (Saisi et al. 2013) clearly indicated that the upper part of the tower is characterized by the presence of several discontinuities due to the historic evolution of the building, local lack of connection, and extensive masonry decay. The poor state of preservation of the same region was confirmed by the observed dynamic characteristics (Saisi et al. 2013), and one local mode involving the upper part of the tower was clearly identified by applying different output-only techniques to the response data collected for more than 24 h on the historic building.

These results clearly highlighted the critical situation of the upper part of the tower, pointing out the need for structural interventions to be carried out. With this motivation, and in order to allow for better indoor inspection of the tower-bearing walls, a metal scaffolding and a light

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 10 Fronts and section of the *Gabbia Tower* (dimensions in m)

wooden roof have been installed inside the tower. Hence, a second dynamic test was performed – aimed at checking the possible effects of scaffolding and wooden roof on the modal characteristics of the structure – and a simple permanent dynamic monitoring system (including three highly sensitive accelerometers and one temperature sensor) was installed in the tower, with structural health monitoring and seismic early warning purposes.

Description of the Tower and On-Site Inspections

The *Gabbia Tower*, about 54.0 m high, is built in solid masonry bricks and has an almost square base; the load-bearing walls are about 2.4 m thick up to the upper levels (Fig. 10) where the thickness of the masonry cross section decreases to about 0.7 m. The top part of the building has a two-level lodge, which hosted in the nineteenth century the observation and telegraph post. A wooden staircase reached the lodge, but it is no more practicable since several years due to the lack of maintenance. The inner access to the tower was reestablished recently (October 2012) through provisional scaffoldings.

The original layout of the surrounding structures is unknown. At present, the tower is part of an important palace, evolved since the thirteenth century, complicating the geometry of the structure and the mutual links.

Few historic documents are available on the past interventions on the tower, but the observation of the masonry texture reveals passing-through discontinuities in the upper region, which are conceivably related to the tower evolution. Traces of past structures are visible on all fronts, and the presence of merlon-shaped discontinuities suggests modifications and further adding at the top of the tower. Moreover, at about 8.0 m from the top, a clear change of the brick surface workmanship (the bricks of the lower part are superficially scratched) could reveal a first addition; in the same region concentrated changes of the masonry texture reveal local repair.

An accurate on-site survey of all fronts of the tower was firstly performed using a mobile platform. The visual inspection, omitting the upper part of the tower (i.e., a portion about 8.0 m high), did not reveal evident structural damage but only superficial decay of the materials (mainly mortar

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 11 Instrumented cross sections and sensors layout during the dynamic tests performed on August and November 2012 (dimensions in m)

joint erosion, due to the natural aging and the lack of maintenance). Subsequent pulse sonic tests, double flat jacks, and laboratory tests on sampled mortars and bricks confirm the soundness and the compactness of the masonry until the height of about 46.0 m. On the contrary, significant damages were observed in the upper 8.0 m of the tower; those damages are related to the abovementioned detachment of the several construction phases and worsened by the natural decay. More specifically, critical areas are the infillings between the merlons, supported only by few courses of thin masonry due to the unusual layout of the scaffolding holes.

Ambient Vibration Testing Procedures and Modal Identification

Two AVTs were conducted on the tower: between 31/07/2012 and 02/08/2012 and on 27/11/2012. It is worth recalling that the second test was performed after the installation of a metallic scaffolding and a wooden roof inside the tower in order to check the possible effects of those additions on the dynamic characteristics of the structure.

The response of the tower was measured in 12 selected points, belonging to 4 different cross sections along the height of the building, according to the sensor layout shown in Fig. 11.

Ambient Vibration Testing of Cultural Heritage Structures,

Fig. 12 Vibration modes generally identified during the first AVT (SSI, 31/07/2012, 21:00–22:00)

It is worth noting that the same cross sections were instrumented in the two tests, but in the second survey the accelerometers were installed on the inner side of load-bearing walls.

In both tests, the excitation was provided only by wind and micro-tremors. In the first test, acceleration data were acquired for 28 h (between 16:00 and 23:00 of 31/07/2012 and from 9:00 of 01/08/2012 to 6:00 of 02/08/2012), and a second acquisition system was used to measure the temperature in three different points of the tower: on the S-W front both indoor and outdoor temperature were measured, whereas only the outdoor temperature was measured on the S-E front. It is worth mentioning that the changes of outdoor temperature were very significant, ranging between 25 °C and 55 °C, whereas slight variations were measured by the indoor sensor (29–30 °C), due to the high thermal inertia of the load-bearing walls.

The modal identification was performed using 3,600 s long time windows and applying the data-driven SSI algorithm available in the Artemis software (SVS 2012).

Figure 12 shows typical results of the first AVT, in terms of natural frequencies and mode shapes. It should be noticed that (a) two closely spaced modes were identified around 1.0 Hz and these modes (Fig. 12a, b) are dominant bending (B) and involve flexure in the two main planes of the tower, respectively; (b) the third mode (Fig. 12c) involves dominant bending in the

N-E/S-W plane with slight components also in the orthogonal N-W/S-E plane; (c) just one torsion mode (T) was identified (Fig. 12d); and (d) the last identified mode is local (L) and only involves deflections of the upper portion of the tower (Fig. 12e).

The presence of a local vibration mode provides further evidence of the structural effect of the change in the masonry quality and morphology observed on top of the tower during the visual inspection. On the other hand, both visual inspection and operational modal analysis confirm the concerns about the seismic vulnerability of the building and explain the fall of small masonry pieces from the upper part of the tower, reported during the earthquake of May 29, 2012.

Statistics of the modal frequencies identified between 31/07/2012 and 02/08/2012 are summarized in columns (2)–(5) of Table 2 through the mean value, the standard deviation, and the extreme values of each modal frequency. It should be noticed that the natural frequencies of all modes exhibit slight but clear variation, with the standard deviation ranging between 0.011 Hz (mode B2) and 0.037 Hz (mode L1). The correlation analysis performed to investigate the possible relationships between natural frequencies and temperature (Saisi et al. 2013) clearly indicated that the natural frequencies of the global modes B1–B3 and T1 increase with increased temperature. This behavior, observed also in previous measurements on masonry structures

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 13 Vibration modes identified during the second AVT (SSI, 27/11/2012)

(Ramos et al. 2010; Gentile et al. 2012), can be explained through the closure of superficial cracks, minor masonry discontinuities, or mortar gaps induced by the thermal expansion of materials. Hence, the temporary “compacting” of the materials induces a temporary increase of stiffness and modal frequencies, as well.

As previously stated, the possible effects of scaffolding and wooden roof on the dynamic characteristics of the tower were investigated in the second AVT, performed on November 27, 2012 with the outdoor temperature being almost constant (10–11 °C). The results of this investigation in terms of identified natural frequencies’ main and mode shapes are shown in Fig. 13 and can be summarized as follows:

1. Beyond the difference in terms of natural frequency (that are conceivably related to the temperature effects), the mode shapes of bending

modes B1–B3 did not exhibit significant changes (see Figs. 12a–c and 13a–c). Hence, the metallic scaffolding and the wooden roof practically do not affect those modes.

2. On the contrary, the mode shape T1 (Fig. 13d) now involves both torsion and bending. The identified frequency did not change appreciably with respect to the first dynamic survey, but the mode shape looks significantly different. The torsion component is still dominant in the lower portion of the structure, while the upper part is characterized by dominant bending with significant components along the two main planes of the tower. In other words, after the installation of the wooden roof, mode shape T1 becomes mixture of previous modes T1 (Fig. 12d, lower part of the structure) and L1 (Fig. 12e, upper part of the structure). Furthermore, the previous mode L1 was no more detected.

3. The previous local mode L1 (Fig. 12e) has been “replaced” by another local mode, with higher frequency of 9.89 Hz, involving torsion of the upper part of the tower (Fig. 13e).

As a further comment, it seems that especially the wooden roof, even if very light, affects the dynamic characteristics of the upper part of the building: the roof acts as a mass directly connected to a highly inhomogeneous and weaker portion of the building, so that a possible decrease of the natural frequency of the previous local mode is generated.

Long-Term Dynamic Monitoring and Typical Results

Few weeks after the execution of the second AVT, a simple dynamic monitoring system was installed in the tower. The system is composed by a 4-channel data acquisition system (24-bit resolution, 102 dB dynamic range, and anti-aliasing filters) with three piezoelectric accelerometers (WR model 731A, 10 V/g sensitivity, and ± 0.50 g peak). The response of the tower is measured in three points, belonging to the cross section at the crowning level of the tower. Furthermore, a temperature sensor is installed on the S-W front, measuring the outdoor temperature.

The digitized data are transmitted to an industrial PC on site. A binary file, containing three acceleration time series (sampled at 200 Hz) and the temperature data, is created every hour, stored on the local PC, and transmitted to Politecnico di Milano for subsequent data processing.

The continuous dynamic monitoring system has been active since December 2012. The data files received from the monitoring system are managed by a software developed in LabVIEW and including the following tasks: (a) creation of a database with the original data (in compact format) for later developments; (b) preliminary preprocessing (i.e., de-trending, automatic recognition and extraction of possible seismic events, creation of one dataset per hour); (c) statistical analysis of data, including the evaluation of averaged acceleration amplitudes and temperature trends; (d) low-pass filtering and decimation of the each dataset; and (e) creation of a second

database, with essential data records, to be used in the modal identification phase. The results of modal identification herein presented were obtained applying the SSI technique.

Figure 14a presents the evolution of the outdoor temperature on the S-W front during the period from 07/01/2013 to 06/04/2013 and shows that the temperature changed between -2 °C and 25 °C with significant daily variations in sunny days.

The identification of the modal frequencies from the datasets collected during the same period provided the frequency tracking shown in Fig. 14b. The inspection of Fig. 14b firstly suggests that the slight fluctuation of the natural frequencies of global modes follows the temperature variation. In order to better explore the temperature effect on the modal frequencies, Fig. 15 presents the first four natural frequencies of the tower plotted with respect to temperature, along with linear best fit lines. The plots in Fig. 15 confirm what already observed in the first dynamic survey: the natural frequencies of the global modes tend to increase with increased temperature almost linearly, as a consequence of the temporary increase of the local stiffness due to the thermal expansion of materials.

The time evolution of the natural frequency of the upper mode, i.e., the local mode L1' (Fig. 13e), deserves some concern because the trend of this modal frequency is very different from the others (Fig. 14b). More specifically, the modal frequency exhibits more significant fluctuations and clearly decreases in time, from an initial value of about 10.0 Hz (07/01/2013) to a final value of about 9.0 Hz at the end of the analyzed period (06/04/2013).

A better inspection of Fig. 14b reveals that two clear drops of the modal frequency took place: (a) between 03/02/2013 and 04/02/2013 and (b) between 14/03/2013 and 15/03/2013. These drops divide the analyzed time period in three parts that are also easily identified by plotting the modal frequency versus the measured outdoor temperature, as shown in Fig. 16. The temperature-frequency plot of Fig. 16 highlights that the clouds of temperature-frequency points corresponding to each of the three different periods are characterized by similar slope of the best fit

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 14 Time evolution of (a) the outdoor temperature measured on the S-W front, (b) the natural frequencies identified with the SSI technique

line, whereas the average frequency value significantly decreases. This behavior suggests the quick progress of a damage mechanism, conceivably related to the worsening of the connection between the wooden roof and the masonry walls, and confirms – once more – the poor structural condition and the high seismic vulnerability of the upper part of the tower, highlighting the urgent need for preservation actions to be performed.

Summary

This entry focuses on the application of ambient vibration testing (AVT) and operational modal analysis (OMA, i.e., the identification of natural

frequencies, mode shapes, and damping ratios from ambient vibration data) to Cultural Heritage structures. Although the topic is rather recent, it is emerging as a subject of great importance in the modern approach to preservation of historic structures.

AVT is a fully nondestructive test, especially suitable to historic structures because it is performed by just measuring the response in operational conditions. In turn, the knowledge of global parameters of the building, such as the modal parameters, provides essential information to validate the numerical models currently used to quantitatively estimate the structural safety of Cultural Heritage structures or to design repair interventions.

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 15 Correlation between the identified modal frequencies and the outdoor temperature (S-W front): (a) mode B1, (b) mode B2, (c) mode B3, (d) mode T1

Ambient Vibration Testing of Cultural Heritage Structures, Fig. 16 Natural frequency of local mode L1' plotted with respect to the outdoor temperature

Furthermore, in some cases, AVT can possibly help also to limit the number of on-site and laboratory tests of materials, which are time-consuming and cost-ineffective. Other possible applications of ambient vibration-based modal analysis in the field of historic structures are for evaluation of the effects of repair interventions or in order to perform dynamics-based damage assessment.

In the first part of this entry, some robust techniques to perform OMA are reviewed, namely, the classical *peak picking* method and the more recent *frequency domain decomposition* and data-driven *stochastic subspace identification*.

Subsequently, the application of these techniques is exemplified with reference to two historic towers. In both cases, notwithstanding the very low level of ambient vibrations that existed during the tests, AVT and OMA have proved to be effective tools for identifying the dynamic characteristics of key vibration modes, provided that appropriate and very sensitive acquisition chain (capable of capturing the “interesting” dynamics embedded in the noise) is used in the tests.

In the first case study (the bell tower of the church *Chiesa Collegiata* in Arcisate, Varese), a rational vibration-based methodology, developed for the calibration of the numerical model, has been discussed as well. The presented methodology – involving systematic manual tuning, sensitivity analysis, and a simple system identification algorithm – provided a linear elastic model of the tower, representing an excellent approximation of the structure in its present condition (i.e., the calibrated model summarizes all the collected documentary and geometric and experimental information and exhibits very good agreement between predicted and measured modal parameters).

In the second case study, typical results from long-term monitoring of the ambient vibration data collected on the *Gabbia Tower* in Mantua, Italy (twelfth century), are summarized. The results clearly demonstrate that the modal identification is capable of highlighting (a) the effects of slight structural modifications; (b) the impact

of temperature on the natural frequencies (i.e., the modal frequencies increase with increased temperature); and (c) the quick progress of a damage mechanism, involving the upper part of the tower, which is clearly identified through the remarkable fluctuations and the significant decrease (about 10 % in 3 months) of the natural frequency corresponding to a local mode.

Analysis and Design Issues of Geotechnical Systems: Flexible Walls

Amir M. Halabian

Non-yielding walls; Retaining flexible walls; Soil thrust

Introduction

The effect of ground motion on rigid retaining walls is examined using the method proposed by Mononobe and Okabe, which is based on the Coulomb's theory of static soil pressure. The analysis and design issues for these walls are covered in a separate companion article. M-O method requires that the retaining walls can move freely (slide or rotate) so that active or passive earth pressures develop behind the wall. Nevertheless, there are many cases (such as basement walls) where the free movement of the wall is fully or

Analysis and Design Issues of Geotechnical Systems: Flexible Walls,
Fig. 1 Walls geometry taken in Wood (1973) analysis of pressures on non-yielding walls

A

partially restrained, referred as non-yielding walls; furthermore, in situ retaining wall systems made from sequential excavation process provide stability and minimize movements of the adjacent ground throughout their flexible facing. In the last decades, a great deal of research work both in the analytical and in experimental areas has been performed to evaluate the adequacy of the M-O method or to extend the method for specific applications such as non-yielding walls or flexible retaining structures. Discussion of the existing approaches to evaluate the seismic soil pressure on non-yielding walls and practical design methods based on limit equilibrium concept and numerical algorithms are described below.

Non-Yielding Walls

Although there are reports of damage and failure on retaining walls due to earthquakes around the world, the distress has been attributed to some form of soil or foundation failure, such as slope instability or soil liquefaction (Al Atik and Sitar 2010). There have been a few reports of damage to building basement walls as a result of seismic earth pressures in recent earthquakes including damages to basements in two recent earthquakes in Turkey. Gur et al. (2009) reported that basement damage occurred in a half-buried basement of a school building during 1999 Düzce earthquake; the half-buried basement was surrounded

by partial height earth-retaining concrete walls and there were windows between the top of the earth-retaining walls and the beams at the top of the basement.

Wood's Method

M-O method requires that the retaining walls can move freely (slide or rotate) so that active or passive earth pressures develop behind the wall. Nevertheless, there are many cases where the free movement of the wall is fully or partially restrained (such as basement walls, massive gravity walls embedded in rock-like formations, and braced walls). Wood (1973) analyzed the response of a homogenous linear elastic soil trapped between two rigid walls connected to rigid base (Fig. 1). In this figure, u , v , and τ_{xy} are referred to the in-plane deformations and shear stresses, respectively.

If both walls are spaced far apart, the pressures on one wall are not influenced by the presence of the other. For low-frequency input motions with frequency less than half the fundamental frequency of the unrestrained backfill, $V_s/4H$ (V_s is the soil shear wave velocity), the pseudo static conditions are governed (i.e., the dynamic amplification is negligible). For this range of frequencies, wall pressures with plane strain assumption can be obtained from elastic solution for the case of a uniform, constant horizontal acceleration applied throughout the soil. The dynamic earth pressures obtained from this method must be

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Fig. 2 Normal wall stresses from Wood's Solution (From Ebeling et al. 1992)

added to the static earth pressures to obtain the total earth pressures during an earthquake. Figure 2 presents two examples of the variation in the values for normalized horizontal stresses with normalized elevations above the base of a wall, based on Wood's solution (Wood 1973). An L/H value of 1 (where L = the width of backfill and H = the wall height) where value of 1 corresponds to a narrow backfill placed within rigid containment, and an L/H value of 10 represents a backfill of great width. The horizontal stresses (σ_x^0) at any vertical location Y, along the wall, are normalized by the product of γH in Fig. 2, where γ is the soil unit weight.

With the assumption of smooth rigid walls, the dynamic thrust and dynamic overturning moment about the base of the wall are expressed as:

$$\Delta F_{eq} = \gamma H^2 \frac{a_h}{g} F_p \quad (1)$$

$$\Delta M_{eq} = \gamma H^3 \frac{a_h}{g} F_m \quad (2)$$

where a_h is the amplitude of the harmonic base acceleration, and F_p and F_m are the dimensionless dynamic thrust and moment factors which can be obtained from Fig. 3. The point of application the dynamic thrust will be located at a height

$$h_{eq} = \frac{\Delta M_{eq}}{\Delta F_{eq}} \quad (3)$$

Ostadan-White Approach

The solution by Wood (1973) commonly used for critical facilities are, in fact, based on static "1g" loading of the soil-wall system and does not include the wave propagation and amplification of motion. On the other hand, Wood's solution is mathematically complicated to apply in engineering practice and is limited to harmonic input motions. Employing the finite element technique, in a simplified method proposed by Ostadan and White (1997) and Ostadan (2004) which incorporates the main parameters affecting the seismic soil pressure for buildings, the lateral seismic soil pressure on these structures

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Fig. 3 Dimensionless thrust and moment factors in Wood's Solution (From Ebeling et al. 1992), ν is the soil Poisson's ratio

can be predicted. The studies showed that seismic soil pressure is affected by the long period part of ground motion and amplified near the resonant frequency of the backfill. The method is focused on the building walls rather than soil-retaining walls and specifically considers the dynamic soil nonlinear properties, relative motion between soil, and the structure and

frequency content of the design motion in its formulation. The method is focused on the building walls rather than soil-retaining walls where the movement of the walls is limited due to the presence of the floor diaphragms representing non-yielding walls. To reach a simplified approach for estimating the lateral seismic pressures on non-yielding walls, Ostadan (2004) performed a series of seismic soil-structure interaction analyses. A typical numerical model of a building basement wall is shown in Fig. 4. The base of the wall is resting on the rock or a firm soil layer.

Having the model shown in Fig. 4 subjected to 1g harmonic acceleration, the frequency contents of the pressure response were evaluated using the pressure transfer functions (TF) amplitude which is the ratio of the amplitude of the seismic soil pressure to the amplitude of the input motion. The pressure transfer functions were evaluated using Poisson's ratio of 1/3 for a wide range of frequencies (Fig. 5a).

If the transfer functions are expressed in terms of normalized frequencies using the soil column frequency which is

$$f_s = V_s / 4H \quad (4)$$

it was shown that the maximum amplifications take place at the frequency corresponding to the soil column frequency (Fig. 5b). V_s is the soil column shear velocity. Comparing the dynamic characteristics of the normalized pressure amplitudes (Fig. 5b), one can conclude that such characteristics are similar to a single degree of freedom (SDOF) system.

For the parametric studies conducted by Ostadan (2004), the results showed that low-frequency pressure profiles depict the same pressure distribution along the height of the wall. In Fig. 6, the soil pressure distribution obtained from such a nonlinear numerical method is compared with the normalized solutions from Wood (1973) and M-O methods. Using the soil pressure distributions obtained from a parametric study, a polynomial relationship has been developed to fit the normalized pressure curves. This relationship is expressed in terms of the

Analysis and Design Issues of Geotechnical Systems: Flexible Walls,
Fig. 4 A typical numerical model of a building basement wall

Analysis and Design Issues of Geotechnical Systems: Flexible Walls,
Fig. 5 Pressure transfer functions (Ostadan (2004))
(a) A typical pressure transfer functions versus frequency (b) Normalized transfer functions versus normalized frequency

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Fig. 6 Normalized pressure distributions (Ostadan (2004))

normalized height, $y = Y/H$ (Y coordinate defined in Fig. 4), as:

$$p(y) = -0.0015 + 5.05y + 15.84y^2 + 28.25y^3 + 24.59y^4 + 8.14y^5 \quad (5)$$

The total thrust applied to the wall is corresponding to the area under the normalized pressure profile curve which can be obtained from the integration of the pressure distribution over the height of the wall. The total area is $0.744H$ for a wall with height H . Keeping in mind that the normalized shape of the pressure distribution is similar to the response of SDOF systems, the amplitudes of the seismic pressure can be obtained from the response spectrum analysis of SDOF systems. Accordingly, the total thrust applied to the wall is subsequently obtained from the product of the total mass in the equivalent SDOF system times the acceleration spectral value at the respective frequency of the system. Having the total thrust, the frequency of

the system and the input motion to the SDOF system, the relationship in the form proposed by Veletsos and Younan (1994) can be used to compute the total mass and the damping of the SDOF system. Therefore, the total mass is obtained from

$$m = 0.5\rho H^2\Psi_v \quad (6)$$

in which ρ is the soil density and Ψ_v is a factor to take into account the Poisson's ratio effect. Since the original study performed for Poisson's ratio equals 1/3 (Ostadan (2004)), the pressure distribution should be adjusted for different Poisson's ratios using a factor recommended by Veletsos et al., Ψ_v , defined as

$$\Psi_v = \frac{2}{[(2-v)(1-v)]^{0.5}} \quad (7)$$

Study of the soil pressure transfer functions and the free-field response motions for wall with height of 50 ft showed that spectral values at the soil column frequency and at 30 % damping have the best correlation with the forces computed directly from the SSI analysis (Ostadan (2004)).

The computational steps of the proposed method by Ostadan (2004) to evaluate the lateral seismic soil pressures applied to the basement walls as a type of the non-yielding wall can be summarized as follows:

- Perform seismic free-field soil column analysis and obtain the acceleration response spectrum at the base of the wall using a free-field analysis code such as SHAKE91 (Schnabel et al. 1972) taking into account soil nonlinearities with input motion specified at the ground surface or at the depth of foundation base mat, $S_{a(\text{free})}$.
- Obtain total mass in the representative SDOF using Eq. 6.
- Obtain the total seismic lateral force by multiplying the mass of the representative SDOF by the spectral amplitude of the free-field response at the soil column frequency.

$$F = m S_{a(\text{free})} \quad (8)$$

- The maximum lateral earth pressure at the ground surface is calculated by dividing the total seismic lateral force by the area under normal soil pressure curve (0.744H).
- The lateral soil pressure distribution along the height of the wall is obtained by multiplying Eq. 5 by the maximum lateral earth pressure at the ground surface.

Soil-Reinforced Walls

Limit Equilibrium Methods

The fundamental stability concept of soil-nailed walls is based on reinforcing soil mass with reinforcement elements such as steel rebars so that the soil mass could behave as a unit mass. Therefore, during an earthquake, in addition to static forces, a reinforced soil wall is subjected to a dynamic soil thrust at the back of the reinforced zone and to internal forces within the reinforced zone. Accordingly, the wall should be designed to have global (external) stability such as avoiding sliding or overturning failure of the reinforced zone as well as local (internal) stability such as avoiding pullout failure of the reinforcement. Stability analyses based on limit-force equilibrium methods have been developed to assess the global static stability of soil-nailed walls along with local stability of reinforced soil mass by taking into account different factors influencing the wall performance, i.e., shearing, tension, and pullout resistance of the inclusions. Therefore, the reinforced wall is treated much like a gravity wall. The reinforced zone recommended by several researchers, shown in Fig. 7, is assumed to be acted on by its own weight, W , and the earthquake loading from unreinforced soil mass represented pseudostatically by dynamic soil thrust, F_D , and the inertial force on the reinforced zone, F_i . The normalized width of the reinforced soil mass, the inertial force on the reinforced zone, and the dynamic soil thrust suggested by Seed and Mitchell (1981), Dhouib (1987) and Segrestin and Bastick (1988) are given in Table 1.

Seed and Mitchell (1981) in their recommendation to FHWA suggested that the reinforced soil area should be taken equal to 0.5H independent of the ground horizontal acceleration, a_h . On the other hand, developing a nonlinear finite element code, Dhouib (1987) showed that the incremental dynamic force is proportional to the distribution of static forces, and the geometry of the active failure zone should be expressed in terms of the system's relative stiffness and the ground acceleration.

Segrestin and Bastick (1988) also conducted finite element analyses to understand seismic response of soil-reinforced structures. In their studies, the elastoplastic behavior of the soil was simulated by varying the modulus of elasticity as a function of observed deformations. The results of the study indicated that the distribution of dynamic tensile forces along the strips is fairly uniform and does not give significant change in the position of points of maximum tension. Unlike the FHWA recommendation, Segrestin and Bastick (1988) suggested that the active failure zone is not affected that much by the earthquake loading, and therefore the width of this area should be limited to 0.3 H. In their studies, the elastoplastic behavior of the soil was simulated by varying the modulus of elasticity as a function of observed deformations. The results of their study indicated that the distribution of dynamic tensile forces along the strips is fairly uniform and does not give significant change in the position of points of maximum tension.

In Table 1, m is the horizontal ground acceleration coefficient calculated at the centroid of the reinforced zone using

$$m = \left(1.45 - \frac{a_h}{g} \right) \frac{a_h}{g} \quad (9)$$

recommended by FHWA.

Pseudostatic Approaches

While limit equilibrium methods fail to give any information regarding developed tensile and shear forces along nails and they cannot evaluate local stability of structure, numerically derived pseudostatic approaches have been developed to investigate behavior of soil-nailed walls under

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Fig. 7 Dynamic soil thrust acting on soil-reinforced walls’ evaluation using different pseudostatic approaches (the symbols are defined in Table 1)

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Table 1 Inertia and dynamic forces applied to the reinforced soil mass

Design method	S/H	Inertial force F_i	Dynamic force F_D
Seed and Mitchell (1981)	0.50	$0.5 m \gamma H^2$	$(3/8) m \gamma H^2$
Dhouib (1987)	$0.30 + m/2$	$\frac{(0.30+m/2)m\gamma H^2}{4(2K+3)}$	—
Se grestin and Bastick (1988)	0.30	$0.20 m \gamma H^2$	$\lambda(3/8) m \gamma H^2$

$K = 2.5 m, \lambda = 0.6$

dynamic-loading conditions. On the other hand, unlike common gravity retaining structures, soil-nailed walls have also shown remarkably well performance during many ground motions,

which could be attributed to the intrinsic flexibility of soil-nailed wall system and possibly some level of conservatism in current design procedures (Choukeir et al. (1997)). Accordingly, as an extension of static limit equilibrium methods, pseudostatic approaches in which dynamic earth pressure is computed based on conventional Mononobe-Okabe approach were developed. Choukeir et al. (1997) presented a new pseudostatic method to analyze soil-nailed slopes. Their proposed approach is derived as an extension of the kinematical working-stress design method developed by Juran et al. (1990) for static loading of soil-nailed structures. The applicability of this working-stress design method under static loading has been described in details by Juran and Elias (1991) and is incorporated in several design codes (FHWA 2003).

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Fig. 8 Pseudostatic method suggested by Choukeir et al. (1997), H_β = the projected height of the inclined wall

The main design assumptions of the kinematical analysis are as follows:

- Failure occurs by a quasi-rigid body rotation of the active zone, which is limited by a log-spiral failure surface.
- The locus of the maximum tension and shear forces at failure coincides with the failure surface developed in the soil mass.
- The shearing resistance of the soil, defined by Coulomb's failure criterion, is entirely mobilized along the sliding surface.
- The shearing resistance of stiff inclusions, defined by Tresca's failure criterion, is mobilized in the direction of the sliding surface in the soil.
- The horizontal components of the inter-slice forces, E_h (see Fig. 8), are equal.
- The effect of a slope (or horizontal surcharge), at the upper surface of the nailed soil mass, on the tension forces in the nails is linearly decreasing along the failure surface.

The extension of the kinematical design method for pseudostatic stability analysis involves the following assumptions:

- The failure-reinforced wedge is subjected to horizontal pseudostatic forces specified as the

mass of the wedge multiplied by the pseudostatic horizontal acceleration $a_h = mg$.

- Shear modulus of the soil is constant along the depth.
- Shear strength parameters of the soil are constant during earthquake loading.
- The soil is not saturated, and thus no effect of pore water pressure is present.
- The failure-reinforced wedge is assumed to be subjected by its own weight, W , and the earthquake loading from unreinforced soil mass represented pseudostatically by dynamic soil thrust, F_D , and its own inertial force, F_i (Fig. 8)

$$K_h = n.m \dots, \dots, n = \frac{a_{ps}}{a_m}$$

$$= \left[\frac{0.5}{1-r^2} \right]^{\frac{1}{2}} \dots, \dots r = \frac{\omega}{\omega_n} \quad (10)$$

Do check that all symbols in Eq. 10 have been defined somewhere else.

Nonlinear Dynamic Analysis Method

As it was presented, there are several pseudostatic methods by which the magnitude of dynamic forces along reinforcements for a soil-nailed structure under dynamic loading conditions could be determined. To get better

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Fig. 9 (a) Model geometry (b) Numerical mesh used for analyses (c) Soil-nailed wall after final stage of excavation (Halabian et al. 2010)

understanding of dynamic response of soil-nailed wall systems under earthquake excitations, a numerical model like what is shown in Fig. 9 for a typical reinforced wall, rather than empirical formulations could be employed to evaluate the wall performance.

To gain better perception of dynamic soil-nailed structures behavior, the numerical model should take into account the wall construction stages which include nail installation and application of shotcrete facing. It should be noted that the model dimensions have to be determined wide enough so that the effects of boundary conditions on the response of structure would be

negligible. Due to repetitive arrangement of nails along the length of the excavation, only a slice of the soil can be modeled (Fig. 9b and c). To have more reliable results of analyses, a somewhat finer mesh should be utilized for those areas near the excavation face. It should be noted that initial state of equilibrium has to be established before any stage proceeds. Afterward as each excavation ends, the equilibrium conditions (according to maximum unbalanced force) will be examined in order to ensure whether or not that model meets the equilibrium conditions to resume the next stage. An appropriate soil constitutive law should be used to simulate the stress

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Fig. 10 Horizontal displacement response time history at the wall head during the harmonic base excitation (Halabian et al. 2010)

path induced to soil mass during the earthquake loading. After static equilibrium is achieved, the full width of soil subgrade should be subjected to dynamic excitations.

Harmonic Ground Excitation

Despite having a single-frequency content and short duration of the excitation, Halabian et al. (2010) used a variable-amplitude harmonic ground motion to understand the effects of crucial parameters on the performance of soil-nailed structure under actual earthquake acceleration records. The accelerogram follows a trend which has both increasing and decaying peak acceleration parts expressed as:

$$\ddot{U}(t) = \frac{1}{2} \left(1 - \cos \left(\frac{2\pi}{T} t \right) \right) \sin(2\pi f t) \quad (11)$$

in which T and f are the duration of net harmonic excitation and the frequency of excitation.

Influence of Harmonic Excitation Frequency The effect of the excitation frequency on the horizontal displacement time histories at the crest of the wall is presented in Fig. 10. The displacement time histories indicate that the horizontal displacement at the crest of the wall was influenced by the excitation frequency and increases monotonically with the time during the harmonic base excitation. However, it can be concluded that as the excitation frequency increases, the horizontal displacement at the

wall crest decreases. Figure 11a indicates that while the input frequency motion increases, the peak outward horizontal displacement of the wall decreases. Conversely, as illustrated by Fig. 11b, the peak horizontal acceleration response along the wall facing is increased by an ascending trend of input motion frequency. From the other results shown in Fig. 12, it is worth noting that increasing input motion frequency made tensile forces to less mobilize along nail bars due to the fact that the critical state becomes more inaccessible since the input motion frequency gets higher than fundamental frequency of the system.

Influence of Angle of Nail Inclination The influence of nail inclination angle on dynamic response of the structure is shown in Fig. 13a. The peak outward horizontal displacement of walls shows decreasing in value by increasing nails inclination angle while it varies in the range of 0–15°. Afterwards, increasing nail inclination angle results in slight increase of wall deformations, especially when it ranges in 25–30°. As a result, it is shown that the increase in nail inclination angle would have destabilizing effect on the performance of structure during harmonic base excitations.

When it comes to the peak horizontal acceleration, as it is demonstrated in Fig. 13b, it can be concluded that increasing nail inclination angle would result in increase of peak horizontal acceleration response of the wall. Figure 14 shows distribution of maximum tensile forces along nail bars.

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Fig. 11 Normalized peak horizontal deformations distribution along height of wall facing (Halabian et al. 2010) (a) Normalized peak horizontal displacement (b) Normalized peak horizontal displacement

Analysis and Design Issues of Geotechnical Systems: Flexible Walls, Fig. 12 Maximum tensile forces distribution along height of wall facing (Halabian et al. 2010)

It is of interest to note that tensile forces along nail bars increase for the upper nail bars as their inclination angle increases.

Influence of Nail Length The effect of nail length on the peak outward horizontal displacement of the wall is shown in Fig. 15a. It can be noted that the peak outward horizontal displacement of the wall decreases as the nails length increases; while, the peak horizontal acceleration along the wall facing has been greater for longer nail bars (Fig. 15b). However, the major influence of nail length on increasing the peak

horizontal acceleration response of the wall would be in the range of 7.5–10 m. Therefore, there would be no considerable influence as the nail length increases beyond the value of 12 m. The results of the maximum nails tensile forces (Fig. 16) indicate that there would be no significant differences in the mobilized maximum tensile forces along nail bars (excluding the third nail) as the nails length increases.

Influence of Soil Strength Properties The soil strength properties, soil friction angle, ϕ , and soil cohesion, c , can also influence on the

Analysis and Design Issues of Geotechnical Systems: Flexible Walls,

Fig. 14 Maximum tensile forces distribution along height of wall facing (Halabian et al. 2010)

wall performance such as horizontal deflections along the wall facing and the maximum mobilized tensile forces along the nail bars during an earthquake. Global performances of soil-nailed walls during earthquakes have shown that increasing in soil strength properties would improve soil shear strength so that soil-nailed wall would better resist against

dynamic loads due to harmonic base excitations. As illustrated in Fig. 17a and b, peak horizontal displacements along wall facing decrease as the soil cohesion and internal friction angle increase. Figure 17c and d show that increasing soil strength properties would result in reduction of maximum tensile forces along nail bars.

Seismic Base Excitations

Similar to the harmonic base excitations, numerous parameters including nails inclination, nails lengths, soil mechanical properties, and nail spacing can contribute to the performance of soil-nailed walls during seismic excitations. In addition to these parameters, the earthquake motions depending on their frequency content and peak amplitude have also substantial influences on deformations of soil-nailed walls.

In a study conducted by Halabian et al. (2010) for a soil-nailed wall example, the effects of three different base excitation records (El Centro, Kobe, and Northridge earthquakes) were examined. It is noteworthy that the ground motion with the frequency content close to the soil-nailed system and higher peak amplitude induced considerable lateral displacements along the wall facing compared to the other ground motions (Fig. 18a).

Analysis and Design Issues of Geotechnical Systems: Flexible Walls,
Fig. 19 Lateral earth pressure distribution behind wall facing along height of wall (Halabian et al. 2010)

Besides, as illustrated in Fig. 18b, earthquake motions with high peak amplitude of base acceleration would cause higher nail forces along nails. There is considerable difference between the values of nail forces in the fifth row of nails. Furthermore, the earth lateral pressure distribution behind the wall facing for different earthquake motions is depicted in Fig. 19, and it can be concluded that earth pressure will increase as the base excitation peak amplitude rises. The observed pattern in earth lateral distribution could be interpreted due to stage construction of soil-nailed structures.

Summary

Several methods to evaluate the maximum seismic soil pressures for some cases (such as basement walls) where the free movement of the wall is fully or partially restrained, referred as non-yielding walls, are presented. Furthermore, based on a comprehensive parametric study, the influence of crucial parameters on performance of soil-nailed walls after being subjected to harmonic and seismic base excitations were also given.

Pseudo-dynamic method; Rigid retaining walls; Yielding walls

Introduction

Earthquakes have caused transient and permanent deformations of retaining structures in past severe earthquakes followed by collapse of walls in some cases. Therefore, knowledge of seismic active earth pressure behind retaining walls is very important in the design of these structures in seismically active regions. This article discusses commonly used pseudo-static approaches such as the Mononobe-Okabe method, which gives the linear distribution of seismic earth pressure on rigid retaining walls in an approximate way. A general pseudo-dynamic method is also

presented to compute the distribution of seismic active earth pressure on a rigid retaining walls supporting cohesionless backfill in more realistic manner by considering time and phase difference within the backfill.

Types of Retaining Walls

Earth retaining structures are structures that can be used to support backfill along a slope or to support an excavation as illustrated in Fig. 1.

Various types of retaining structures are adopted for different applications. Over the time, the classical gravity rigid retaining walls evolved into reinforced concrete cantilever walls (e.g., sheet piles), with or without buttresses and counter forts (Fig. 2). These were then followed by a variety of crib- and bin-type walls. All these walls are externally stabilized walls or conventional gravity retaining walls.

In order to stabilize the deep excavation projects in metropolitan areas or even slopes where sequential construction in comparison with other common retaining walls is beneficial, the flexible retaining structures could be considered. During the sequential excavation, an in situ flexible retaining wall system is constructed to provide stability and to minimize movements of the adjacent ground. Soldier piles with shotcrete lagging are being used extensively as an excavation support system, particularly in stiff soil conditions and where ground water ingress into the excavated area is not problematic (Tomlinson 1995). Furthermore, since the soldier piles are not contiguous, much fewer soldier piles often need to be driven in comparison with sheet piles, thereby yielding significant savings in time and cost of installation and thus allowing excavation to commence with a minimum of lead time. These systems are usually being constrained against certain types of movements by the presence of external bracing elements such as struts (Figs. 3 and 4). In the case of basement walls or bridge abutments, lateral movements at the top of the retaining structure are restrained by the presence of the structure they support.

Soil reinforcement in various constructions is also used to provide the stability for excavations

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 1 Gravity retaining structures

and is proven to be effective and under practice from the last two decades. Among the reinforced soil retaining structures, geosynthetic reinforced soil retaining walls with modular block facing are functioned well during the past seismic events compared to the other flexible retaining walls. The reinforced layers of soil in the mechanically stabilized earth mass made with this technique allow the modular construction, which was clearly recognized as being advantageous in most practical situations (Fig. 5).

Soil nailing is another in situ reinforcing technique of the soil while it is excavated from the top down. Using soil-nailed walls which consist of passive reinforcement to the existing ground by installing closely spaced steel bars or cables encased in grout has gained a lot of popularity in recent years (Fig. 6). This method is typically used in order to stabilize slopes and excavations where sequential construction is beneficial in comparison with other common retaining walls. The mass of reinforced soil made by an array of soil nails functions to retain the less stable material behind it. In the right soil conditions, soil nailing is a rapid and economical means of constructing excavation support systems and retaining walls. The process of construction of soil-nailed walls commonly involves three important stages: excavation, nail installation, and face stabilization. The fundamental stability concept of soil-nailed walls is based on reinforcing soil mass with reinforcement elements such as steel rebars so that the soil mass could behave as a unit mass.

Due to significant flexibility of soil-nailed walls which is attributed to particular construction procedure of these systems, soil-nailed walls can experience more deflections comparing with other common gravity walls. After the 1989 Loma Prieta, 1995 Kobe, and 2001 Nisqually earthquakes, it was reportedly observed that soil-nailed walls have shown no sign of being

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 2 Cantilever retaining structures

distressed or significant permanent deflection, despite having experienced, in some cases, ground accelerations as high as 0.7 g. The observations from post-earthquake investigations imply that soil-nailed walls appear to have an inherent satisfactory seismic response. This has been attributed to the intrinsic flexibility of soil-nailed wall system and possibly some level of conservatism in current design procedures (Choukeir et al. (1997)).

Although soil nailing is now recognized as a viable technique in retaining structures, tiebacks have been used and continue to be employed as a temporarily supporting system for excavations. Permanent tieback walls have been used in cuts, bridge abutments, underpinning of structures, and stabilization of sliding slopes. Essentially, there are two types of tieback walls: the slurry wall that is also called diaphragm wall and the soldier pile wall. The main advantage of using soldier piles is their relatively low cost and ease of installation, compared to other forms of supporting systems such as diaphragm walls and bored piles.

Furthermore, since the soldier piles are not contiguous, much fewer soldier piles often need to be driven in comparison to sheet piles. The soldier pile walls are built by driving piles (usually H-piles) in a line with spacing of the order of 2–3 m. Soldier piles are driven to a depth slightly below the final excavation. Sometimes bored piles are used by drilling a hole, lowering an H-pile in the center and filling the annulus with low strength concrete.

steps

As excavation proceeds, wood lagging or sheeting (concrete shotcrete) is placed to retain the soil between the piles. Then, the anchors are installed at regular intervals and grouted in a zone beyond

the failure zone. The anchors are stressed up to a chosen load when the grout has sufficiently cured. The process continues until the final excavation level is reached. Tiebacks eliminate

Analysis and Design Issues of Geotechnical Systems: Rigid Walls,
Fig. 5 Geosynthetic reinforced soil retaining wall with modular block facing

Analysis and Design Issues of Geotechnical Systems: Rigid Walls,
Fig. 6 Soil-nailed walls

obstructions in the excavation inherent in struts. The total structural system acts in tension and receives its support in earth and, therefore, consists of the earth mass, which provides the ultimate support for the system, tension members which transfers the load from the soil-retention system to the earth mass. A stressing unit, which engages the anchors, permits the tieback element to be stressed and allows the load to be maintained in the tieback. A typical tieback wall is shown in Fig. 7.

Depending on soil-induced deformation values, earth retaining structures are broadly categorized into non-yielding, yielding, and self-yielding walls. Non-yielding walls are inherently incapable of and/or constrained against both deformation and displacement in the horizontal direction under static or dynamic loads. Basement walls of buildings, bridge abutments, and free-standing retaining walls that are restrained against horizontal displacement due to physical restraint or structure geometry can be named as

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 7 Tieback retaining system

the common examples. In the static loading phases, non-yielding structures can be logically designed assuming the at-rest earth pressure state within the retained soil. However, in the metropolitan areas where one major concern with deep excavations is the potentially large ground deformations in and around the excavation resulting damages to the adjacent buildings and utilities, there are many uncertainties corresponding to the calculation of the lateral earth pressure distribution of braced excavation systems. While active and passive earth pressure theory is applicable in simple cases, multilevel braced excavations tend to experience more complex earth pressures.

Yielding walls define earth retaining systems that can either displace or deform or both in the horizontal direction under design loads. For rigid retaining walls, the deformation mode shapes could be translation, rotation, or both (Fig. 8). These structures are assumed to be capable of developing the active or passive earth pressure states within the retained soil. The third type of earth retaining structures is so-called self-yielding rigid walls whose as a result of thermal changes in their surrounding environment displace horizontally on their own as opposed to displacing (or not) as a reaction from earth loads as in the classic cases of yielding and non-yielding earth retaining walls. Examples include various types of circular water- and wastewater-treatment tanks (Horvath 2005).

Dynamic Earth Pressure on Rigid Retaining Structures

Design of retaining structures to sustain strong earthquakes may further assure the efficient functioning of these structures. Among several aspects to be considered for seismic design of these structures, seismic lateral earth pressure on rigid walls is the important parameter for designing proper reinforcement materials and configuration. Earth pressure theories associated with conventional rigid retaining walls which are based on limit state analysis of yielding walls on the static conditions can be extended to the dynamic states. According to IBC 2006, the natural frequency (in terms of Hz) of a retaining wall with height H can be roughly calculated by

$$f = \frac{20}{H^{0.75}} \quad (1)$$

in which H is the height of the wall in meter. If the natural frequency of wall is considerably larger than the frequency of the input motion applied to the wall, the soil structure system could be assumed to be rigid, and therefore, earth pressure theories, hereafter, are applicable. Methods that are commonly used for design of retaining walls could be classified as force-based methods developed on limit state analysis basis and performance-based approaches.

Force-Based Method

Increasing lateral earth pressures on retaining walls during earthquakes has been one of the major causes of their damage and excessive displacement (Seed and Whitman 1970; Dakoulas and Gazetas 2008). Therefore, correct estimation of the active earth pressure distribution acting on retaining walls during earthquakes is vital for evaluating the safety and designing of the wall. Some simplified approaches have been proposed to calculate the rather complicated dynamic earth pressures on retaining walls during earthquakes (Okabe 1926; Mononobe and Matsuo 1929; Wood 1973;

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 8 Deformation mode shapes for yielding rigid retaining walls

Steedman and Zeng 1990; Richards et al. 1999; Choudhury and Singh 2006; Ghosh 2008).

Mononobe-Okabe Approach

Okabe (1926) and Mononobe and Matsuo (1929) extended Coulomb's theory and considered seismic forces by applying earthquake loads as pseudo-static inertial forces to the Coulomb active or passive failure wedge. This pseudo-static method (known as the Mononobe-Okabe method) has been widely used in practical applications (Mylonakis et al. 2007) and is recommended by several building codes and guidelines (e.g., EAU 1996; FHWA 1997; CHBDC 1998; ASCE 4-98 2000; FEMA 369 2000; PIANC 2001; EN 1997 2002; AASHTO 2006; IBC 2006) because of its simplicity in practical applications and reasonable predictions of the actual dynamic pressures acting on walls (Seed and Whitman 1970; Whitman 1990; Ebeling et al. 1992; Veletsos and Younan 1994; Dakoulas and Gazetas 2008).

The dynamic lateral earth pressure on rigid retaining structures proposed in the Mononobe-

Okabe method is obtained from the equilibrium of the active or passive wedges (Fig. 9a and b). In addition to the forces that exist under static conditions of the failure wedge in a dry, cohesionless backfill, the wedge is also subjected to horizontal and vertical pseudo-static forces specified as the mass of the wedge multiplied by pseudo-static accelerations $a_h = k_h g$ and $a_v = k_v g$. The total active and passive thrusts on a rigid wall retaining a dry, cohesionless backfill can be presented in a form similar to what is developed for the static conditions in the Coulomb's theory:

$$P_{AE} = \frac{\gamma_b H^2}{2} (1 - k_v) K_{AE} \quad (2)$$

$$P_{PE} = \frac{\gamma_b H^2}{2} (1 - k_v) K_{PE} \quad (3)$$

in which γ_b is the backfill unit weight, H is the height of the wall, and P_{AE} and P_{PE} are the dynamic active and passive earth pressures. K_{AE} and K_{PE} are the coefficient of dynamic active and passive earth pressures given by:

$$K_{AE} = \frac{\cos^2(\varphi_b - \varphi - \beta)}{\cos \varphi \cos^2 \beta \cos(\delta + \varphi + \beta) \left(1 + \sqrt{\frac{\sin(\varphi_b + \delta) \sin(\varphi_b - \varphi - i)}{\cos(\delta + \beta + \varphi) \cos(i + \beta)}} \right)^2} \quad (4)$$

$$K_{PE} = \frac{\cos^2(\varphi_b - \varphi + \beta)}{\cos \varphi \cos^2 \beta \cos(\delta + \varphi - \beta) \left(1 - \sqrt{\frac{\sin(\varphi_b + \delta) \sin(\varphi_b - \varphi + i)}{\cos(\delta - \beta + \varphi) \cos(i + \beta)}} \right)^2} \quad (5)$$

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 9 Mononobe-Okabe approach's failure wedges. (a) Forces acting on active wedge in

Mononobe-Okabe analysis. (b) Forces acting on passive wedge in Mononobe-Okabe analysis

ϕ_b is the internal friction angle of the backfill. i is the slope of the backfill with respect to the horizontal axis. δ is the friction angle between the inner face of the wall and the backfill. β is the angle between the inner face of the wall and the vertical axis. $\varphi = \tan^{-1} \frac{k_h}{1-k_v}$ in which k_h and k_v stand for the horizontal and vertical accelerations of the soil wedge in g unit. The wall is unstable when k_h is higher than $(1-k_v) \tan \varphi$. During the earthquake, k_h and k_v are time varying and chaos so that the seismic earth pressures in both active and passive cases are not constant. The vertical ground excitation has a great influence on dynamic stability of rigid retaining structures during an earthquake. Despite time-varying nature of ground excitations accelerations, the vertical accelerations of earthquakes usually assumed to be a fraction of their horizontal accelerations.

Although the Mononobe-Okabe method suggests that the total dynamic lateral earth pressure on rigid retaining structures should apply at a point $H/3$ above the base of the wall of height, H , experimental results demonstrated that it actually occurs at the higher point under dynamic loading conditions (Fig. 10). The total dynamic lateral earth pressure can be divided into the static active or passive

component, P_A or P_P , and the dynamic contribution, ΔP_{AE} or ΔP_{PE} :

$$P_{AE} = P_A + \Delta P_{AE}, P_{PE} = P_P + \Delta P_{PE} \quad (6)$$

According to the Coulomb theory for linear backfill surfaces with no surcharge loading, the static component acts at a point located $H/3$ above the height of the wall. On the other hand, the dynamic part can be taken to act at a point approximately $0.6H$ above the base of the wall (Seed and Whitman 1970). Therefore, the total lateral earth pressure is applied at a height:

$$h = \frac{P_A (H/3) + \Delta P_{AE} (0.6H)}{P_{AE}} \quad (7)$$

above the base of the wall.

Effects of Water on Dynamic Lateral Pressures

Hydrodynamic Pressure

The retaining walls in practice are usually designed with drainage systems to prevent water from building up. In these cases, the dynamic lateral earth pressure can be

**Analysis and Design
Issues of Geotechnical
Systems: Rigid Walls,

total active thrust

**Analysis and Design
Issues of Geotechnical
Systems: Rigid Walls,
Fig. 11** Acting point of the
total active thrust

determined based on soil dry unit weight using the Mononobe-Okabe theory. However, the presence of water in retaining walls in water-front areas and in backfills behind retaining walls can play a significant role in determining seismic loads that act on the wall during and after earthquakes. During any ground

excitations, besides the hydrostatic pressure, p_{ws} , water in front of a retaining wall will exert dynamic pressures, p_{wd} , on the face of the wall (Fig. 11). The hydrostatic pressure is calculated by

$$p_{ws}(x) = \gamma_w x \quad (8)$$

in which γ_w is the water unit weight and x is the distance from the reservoir surface. The total hydrostatic thrust is then determined as

$$P_{ws} = \int_0^H p_{ws}(x) dx = \frac{1}{2} \gamma_w H^2 \quad (9)$$

The application point of the hydrostatic thrust is a point $H/3$ above the base of the wall of height, H .

Hydrodynamic pressure results from the seismic response of the water mass in front of the wall and is usually estimated using Westergaard's theory (Westergaard 1931). Westergaard's theory applies for a vertical rigid wall retaining a very large (theoretically infinite) extent of water basin with no backfill horizontally excited by harmonic motion of its rigid base. The amplitude of hydrodynamic pressure is then determined using Westergaard's theory as

$$p_{wd}(x) = \frac{7}{8} k_h \gamma_w H \sqrt{x/H} \quad (10)$$

The resultant hydrodynamic force is obtained as

$$P_{wd} = \int_0^H p_{wd}(x) dx = \frac{7}{12} k_h \gamma_w H^2 = (1.17 k_h P_{ws}) \quad (11)$$

According to Westergaard's theory, the hydrodynamic thrust can be taken to act at a point approximately $0.4H$ above the base of the wall. The excess hydrodynamic pressures could be applied toward or outward the wall depending on the base excitation direction. Thus, the direction of the excitation should be taken into account in determining the total hydrodynamic pressure acting on the wall.

Effect of Wall Inclination

The hydrodynamic pressure on the walls with facing inclination (Fig. 12) could be estimated taking the wall inclination using Zangar (1953) and Chwang (1978):

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 12 Effect of wall inclination on hydrodynamic pressure

$$p_{wd}(x, \alpha) = C_m(\alpha) k_h \gamma_w H \left[\frac{x}{H} \left(2 - \frac{x}{H} \right) + \sqrt{\frac{x}{H} \left(2 - \frac{x}{H} \right)} \right] \quad (12)$$

or approximately using Westergaard's approach can be estimated by

$$p_{wd}(x, \alpha) = \frac{7}{8} C_m(\alpha) k_h \gamma_w H \sqrt{x/H} \quad (13)$$

in which $C_m(\alpha)$ is the inclination factor given by

$$C_m(\alpha) = 2.0 \frac{\alpha}{\pi} \quad (14)$$

The total hydrodynamic thrust considering the wall inclination acts at a point located $0.4H$ above the base of the wall of height, H with amplitude

$$P_{wd}(\alpha) = \frac{7}{12} C_m(\alpha) k_h \gamma_w H^2 = (1.17 C_m(\alpha) k_h P_{ws}) \quad (15)$$

Effect of Water Basin Length

Westergaard's theory was developed based on this assumption that the rigid wall is retaining a semi-infinite reservoir of water. For the case a finite water basin (Fig. 13), the hydrodynamic pressure applied to the wall can be evaluated using Werner and Sundquist's (1943) suggestion by intruding the water basin length modification factor, C_n , as

$$p_{wd}(x) = \frac{7}{8} C_n k_h \gamma_w H \sqrt{x/H} \quad (16)$$

**Analysis and Design
Issues of Geotechnical
Systems: Rigid Walls,
Fig. 13** Wall retaining
finite water basin

A

where C_n is defined in terms of ratio of water basin length, L , over the wall height, H , as

$$C_n = \frac{4}{3} \frac{L/H}{1 + L/H} \leq 1.0 \quad (17)$$

$$C_n = 1.0 \quad L/H \geq 2.7$$

The total hydrodynamic thrust considering the water basin length effect acts at a point located $0.4H$ above the base of the wall of height, H with amplitude

$$P_{wd} = \frac{7}{12} C_n k_h \gamma_w H^2 = (1.17 C_n k_h P_{ws}) \quad (18)$$

Dynamic Pressure for Saturated Backfill

Seismic response of rigid walls retaining saturated backfills could be affected by the presence of water changing the inertial forces within the backfill, developing the hydrodynamic pressures with the saturated soil and generating excess pore water pressure resulting in the cyclic deformation of the backfill soil (Matsuo and Ohara 1965). The soil permeability plays an important role in developing hydrodynamic pressures within the backfill soil. For soils with small permeability, the pore water moves within the soil in restrained conditions during the ground shaking; while if the permeability of the backfill is very high, the soil particles move easily through the pore water, and the pore water may remain stationary. Hydrodynamic water

pressures resulting from the seismic response of the water in the backfill soils could be estimated by Westergaard's theory modifying the effect of the soil permeability as

$$P_{wd}(x) = \frac{7}{8} C_e k_h \gamma_w H \sqrt{x/H} \quad (19)$$

in which C_e is the correction factor that expresses the portion the pore water which vibrates freely within the soil:

$$C_e = 0.5 - 0.5 \tan h \left[\log \frac{2\pi n \gamma_w H^2}{7E_w K T} \right] \quad (20)$$

where n is the porosity, H is the water depth, E_w is the bulk modulus of water (2×10^6 kPa), K is the backfill permeability, and T is the predominant period of the excitation (Fig. 14).

The total hydrodynamic thrust considering the water within the backfill acts at a point located $0.4H$ above the base of the wall of height, H with amplitude

$$P_{wd} = \frac{7}{12} C_e k_h \gamma_w H^2 = (1.17 C_e k_h P_{ws}) \quad (21)$$

Earth Lateral Pressures on Walls Retaining Saturated Backfills

For walls retaining saturated soils with restrained pore water conditions, to take into account the presence of water within the backfill, the Mononobe-Okabe approach is modified using

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 14 Wall retaining saturated backfill

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 15 Physical analogy proposed by Matsuzawa et al. (1985)

physical analogy proposed by Matsuzawa et al. (1985). The dynamic lateral pressures act on a yielding wall are coming from the soil skeleton, the trapped water which vibrates together with the soil skeleton and free water which vibrates independently from the soil skeleton (Fig. 15). The total active static soil thrust acts at a point located $H/3$ above the height of the wall can be evaluated as

$$P_A = \frac{1}{2} k_A (\gamma_{\text{sat}} - \gamma_w) H^2 \quad (22)$$

Besides the hydrostatic force exerted on the wall, the hydrodynamic pressures considering the wall facing inclination, the water basin length, and the saturated backfill resulting from the seismic response of the water in the backfill soil could be estimated as

$$p_{\text{wd}}(x) = \frac{7}{8} C_n C_m C_e k_h \gamma_w H \sqrt{x/H} \quad (23)$$

and the total hydrodynamic thrust acts at a point located $0.4H$ above the base of the wall (Fig. 16) and is determined by

$$P_{\text{wd}} = \frac{7}{12} C_n C_m C_e k_h \gamma_w H^2 \quad (24)$$

$$H^2 = (1.17 C_n C_m C_e k_h P_{\text{ws}})$$

If the total dynamic earth pressure coefficient, K_{AE} , is written as

$$K_{\text{AE}} = K_A + \Delta K_{\text{AE}}$$

and using an approximation for ΔK_{AE} equal to $(3/4)k_h$ suggested by Seed and Whitman, therefore, the dynamic lateral force component for a rigid wall retaining dry backfill soil would be

$$\Delta P_{\text{AE}} = \frac{1}{2} \gamma H^2 \Delta K_{\text{AE}} = \frac{1}{2} \left(\frac{3}{4} k_h \right) \gamma H^2 \quad (25)$$

For saturated backfill soil, the dynamic component of the earth thrust acting on the wall (Fig. 16), employing $\gamma^* = C_e \gamma_{\text{dry}} + (1 - C_e) \gamma_{\text{sat}}$, should be computed as

$$\Delta P_{\text{AE}} = \frac{1}{2} \left(\frac{3}{4} k_h \right) \gamma^* H^2 \quad (26)$$

P_A computation requires $\gamma_{\text{sat}} - \gamma_w$, while γ^* should be used in determining ΔP_{AE} . However, sometimes it is necessary to compute

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 16 Different components of acting thrust on the wall

P_A and ΔP_{AE} with a common unit weight (e.g., EAK 2002). In this case, the buoyant unit weight, $\gamma_{sat} - \gamma_w$, and a modified seismic coefficient as

$$k^* = k \frac{\gamma^*}{\gamma_{sat} - \gamma_w} \quad (27)$$

For impermeable soils such as clayey sand, clayey silts, and clayey gravels, $C_e = 0$, and therefore, should be used $\gamma^* = \gamma_{sat}$ resulting $P_{wd} = 0$ and

$$\Delta P_{AE} = \frac{1}{2} \left(\frac{3}{4} k_h \right) \gamma_{sat} H^2 \quad (28)$$

or

$$\Delta P_{AE} = \frac{3}{8} \left(k_h \frac{\gamma_{sat}}{\gamma_{sat} - \gamma_w} \right) (\gamma_{sat} - \gamma_w) H^2 \quad (29)$$

On the other hand, for permeable soils such as sands, gravels, and cobbles, $C_e = 1$, and therefore, $\gamma^* = \gamma_{dry}$ resulting

$$P_w = \frac{1}{2} \gamma_w H^2, P_{wd} \neq 0$$

$$\Delta P_{AE} = \frac{1}{2} \left(\frac{3}{4} k_h \right) \gamma_{dry} H^2 \quad (30)$$

or

$$\Delta P_{AE} = \frac{3}{8} \left(k_h \frac{\gamma_{dry}}{\gamma_{sat} - \gamma_w} \right) (\gamma_{sat} - \gamma_w) H^2 \quad (31)$$

In other approach, by representing the excess pore water pressure in the backfill using the pore pressure ratio, r_u , the active earth pressure acting on wall with cohesionless backfill can be computed using

$$p_{AE} = K_{AE} \gamma_{sub} (1 - r_u) (1 - k_v)$$

$$\phi = \tan^{-1} \left[\frac{\gamma_{sat} k_h}{\gamma_{sub} (1 - r_u) (1 - k_v)} \right] \quad (32)$$

Steedman-Zeng Method

The dynamic nature of earthquake loading in M-O method is considered in a very approximate way without taking any effect of time. To reach the dynamic response characteristics of rigid walls during an earthquake taking into account the phase difference due to finite shear wave propagation within the backfill soil, Steedman and Zeng (1990) proposed a simple pseudo-dynamic approach to determine the seismic response of fixed-base cantilever walls subjected to a harmonic horizontal acceleration considering finite shear wave velocity within backfill material. Choudhury and Nimbalkar (2006) extended the Steedman-Zeng approach to take into account the wall friction angle, soil

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 17 Retaining wall considered for computation of pseudo-dynamic active earth pressure

friction angle, shear wave velocity (V_s), primary wave velocity (V_p), and both the horizontal and vertical seismic accelerations ($k_h g$ and $k_v g$) on the seismic active earth pressure behind the wall (Fig. 17).

If the retaining wall is subjected to both the horizontal and vertical seismic accelerations ($k_h g$ and $k_v g$), the accelerations at any depth z and time t , below the top of the wall, can be expressed as

$$\begin{aligned}\ddot{u}(z, t) &= k_h g \sin \left[\omega \left(t - \frac{H - z}{V_s} \right) \right] \\ \ddot{v}(z, t) &= k_v g \sin \left[\omega \left(t - \frac{H - z}{V_p} \right) \right]\end{aligned}\quad (33)$$

The mass of a thin element of wedge at depth z is

$$m(z) = \gamma_b \frac{H - z}{g \tan \alpha} dz \quad (34)$$

The total horizontal and vertical inertial forces acting within the failure zone can be expressed as

$$\begin{aligned}F_h(t) &= \int_0^H m(z) \ddot{u}(z, t) dz \\ &= \frac{\lambda \gamma_b k_h}{4\pi^2 \tan \alpha} [2\pi H \cos \omega \zeta + \lambda (\sin \omega \zeta - \sin \omega t)]\end{aligned}$$

$$\begin{aligned}F_v(t) &= \int_0^H m(z) \ddot{v}(z, t) dz \\ &= \frac{\eta \gamma_b k_v}{4\pi^2 \tan \alpha} [2\pi H \cos \omega \psi + \eta (\sin \omega \psi - \sin \omega t)]\end{aligned}\quad (35)$$

where $\lambda = 2\pi V_s / \omega$ is the wavelength of the vertically propagating shear wave, $\zeta = t - H/V_s$, $\eta = 2\pi V_p / \omega$ is the wavelength of the vertically propagating primary wave, and $\psi = t - H/V_p$. For rigid wedge, the shear wave velocity and the primary wave velocity tend to infinite, and total horizontal and vertical inertial forces will be equivalent to the pseudo-static force assumed in the Mononobe-Okabe method. The total (static + seismic) active thrust, $P_{AE}(t)$, can be obtained by resolving the forces on the wedge and considering the equilibrium of the forces, and hence $P_{AE}(t)$ can be expressed as follows:

$$P_{AE}(t) = \frac{F_h(t) \cos(\alpha - \phi_b) + W \sin(\alpha - \phi_b) - F_v(t) \sin(\alpha - \phi_b)}{\cos(\delta + \phi_b - \alpha)} \quad (36)$$

The seismic active earth pressure coefficient, K_{AE} , is defined as

$$K_{AE} = \frac{2P_{AE}}{\gamma_b H^2} \quad (37)$$

Substituting for F_h and F_v , K_{AE} is derived as

$$\begin{aligned}K_{AE} &= \frac{1}{\tan \alpha} \frac{\sin(\alpha - \phi_b)}{\cos(\delta + \phi_b - \alpha)} \\ &+ \frac{k_h}{2\pi^2 \tan \alpha} \left(\frac{2\pi V_s}{\omega H} \right) \frac{\cos(\alpha - \phi_b)}{\cos(\delta + \phi_b - \alpha)} m_1 \\ &- \frac{k_v}{2\pi^2 \tan \alpha} \left(\frac{2\pi V_p}{\omega H} \right) \frac{\sin(\alpha - \phi_b)}{\cos(\delta + \phi_b - \alpha)} m_2\end{aligned}\quad (38)$$

where

$$m_1 = \left[2\pi \cos 2\pi \left(\frac{t\omega}{2\pi} - \frac{H\omega}{2\pi V_s} \right) + \left(\frac{2\pi V_s}{H\omega} \right) \left(\sin 2\pi \left(\frac{t\omega}{2\pi} - \frac{H\omega}{2\pi V_s} \right) - \sin 2\pi \left(\frac{t\omega}{2\pi} \right) \right) \right]$$

$$m_2 = \left[2\pi \cos 2\pi \left(\frac{t\omega}{2\pi} - \frac{H\omega}{2\pi V_p} \right) + \left(\frac{2\pi V_p}{H\omega} \right) \left(\sin 2\pi \left(\frac{t\omega}{2\pi} - \frac{H\omega}{2\pi V_p} \right) - \sin 2\pi \left(\frac{t\omega}{2\pi} \right) \right) \right]$$

(39)

From the above equation, it can be noted that K_{AE} is function of the dimensionless parameters $\frac{H\omega}{2\pi V_s}$, $\frac{H\omega}{2\pi V_p}$, $\frac{t\omega}{2\pi}$, and the wedge angle, α . The maximum value of K_{AE} is obtained by optimizing K_{AE} with respect to $\frac{t\omega}{2\pi}$ and α . This parameter would be a function of $\frac{H\omega}{2\pi V_s}$ and $\frac{H\omega}{2\pi V_p}$ which is the ratio of time for shear wave and primary wave to travel the full height of the wall to the period of lateral shaking.

The seismic active earth pressure distribution can be obtained by differentiating the total active thrust as

$$P_{AE}(t) = \frac{\partial P_{AE}(t)}{\partial z} = \frac{\gamma z}{\tan \alpha \cos(\delta + \phi_b - \alpha)} \frac{\sin(\alpha - \phi_b)}{\cos(\delta + \phi_b - \alpha)} + \frac{k_h \gamma z}{\tan \alpha \cos(\delta + \phi_b - \alpha)} \sin \left[\omega \left(t - \frac{z}{V_s} \right) \right] - \frac{k_v \gamma z}{\tan \alpha \cos(\delta + \phi_b - \alpha)} \sin \left[\omega \left(t - \frac{z}{V_p} \right) \right]$$

(40)

Design earth pressures determined by the Steedman-Zeng method or in general by Choudhury-Nimbalkar that account for backfill amplification should be considered for design of unusually displacement-sensitive walls such as tall retaining gravity walls.

Performance-Based Design

The observations after severe earthquakes have shown that retaining walls could fail during earthquakes by sliding away from the backfill or due to combined action of sliding and rocking displacements, while the post-event serviceability of such structures is also related to the wall displacements induced by the earthquake. Accordingly, any approaches that predict post-earthquake wall displacements should provide a more indication of retaining walls performances. Therefore, an alternative design approach, so-called performance-based design, could be used on the basis of permanent displacements for the wall when selecting an allowable displacement for design.

Performance-based design of retaining walls must account for the likely displacements the retaining wall may experience during an earthquake in addition to calculating the usual factors of safety against failure in bearing capacity, sliding, and overturning. There are several procedures available such as Richard and Elms (1979), Whitman and Liao (1985), and Wu and Prakash (2001) to estimate the permanent displacements of rigid walls.

In the Richards-Elms method, only the displacements of the sliding modes are taken into account. Considering the gravity rigid wall shown in Fig. 18, when the active backfill edge is subjected to ground acceleration toward the backfill, the resulting inertial forces will act away from the backfill. Therefore, in the limit state of sliding motion where the level of ground acceleration, so-called yield acceleration, is large enough to cause the wall to slide on its base, the horizontal and vertical equilibrium equations are

$$T = F_h + (P_{AE})_h$$

$$N = W + (P_{AE})_v$$

(41)

Analysis and Design Issues of Geotechnical Systems: Rigid Walls, Fig. 18 Gravity retaining wall considered in Richard-Elms method

Substituting $T = N \tan \phi_b$, $F_h = a_y W/g$, $(P_{AE})_h = P_{AE} \cos(\delta + \beta)$, and $(P_{AE})_v = P_{AE} \sin(\delta + \beta)$, the yield acceleration can be computed by

$$a_y = \left[\tan \phi_b - \frac{P_{AE} \cos(\delta + \beta) - P_{AE} \sin(\delta + \beta)}{W} \right] g \quad (42)$$

In calculating P_{AE} , since the M-O method requires that a_y be known, the solution of the above equation must be obtained iteratively. In the Richard-Elms, based on the sliding block analysis, the permanent block displacement is determined as

$$\delta = 0.087 \frac{V_{\max}^2}{\alpha_{\max}} \left(\frac{a_y}{a_{\max}} \right)^{-4} \quad (43)$$

where $V_{\max}$ is the peak ground velocity and $a_{\max} = k_h g$ is the horizontal peak ground acceleration.

A realistic model for estimating the dynamic displacement must account for the combined action of possible displacement modes including sliding and rocking vibrations and considering (1) soil stiffness in sliding and rocking, (2) geometrical and material damping in sliding and rocking, and (3) nonlinear coupling effects for stiffness and damping. Wu and Prakash (2001) proposed a model for simulating the response of rigid retaining walls subjected to seismic loading. This model (Fig. 19) consisted of a rigid wall resting on the foundation soil and subjected to a horizontal ground motion and analyzed the problem as a case of combined sliding and rocking vibrations including the effect of various important parameters such as soil stiffness in sliding, soil stiffness in rocking, geometrical damping in sliding, geometrical damping in rocking, material damping in sliding, and material damping in rocking.

An important step in the performance design procedure is the selection of the permissible displacement. There are some guidelines given available based on experience or judgment (Huang 2005). Eurocode (1994) gives the permissible horizontal displacement equal to $300 a_{\max}$ (mm) where $a_{\max}$ is the maximum horizontal design acceleration, while AASHTO (2006) suggests this parameter to be limited to $250 a_{\max}$ (mm). Wu and Prakash (1996) proposed that the permissible horizontal displacement should be 2 % of the height of the retaining wall, H , while the failure horizontal displacement is equal to $0.1H$. According to the Japanese Railway Technical Research Institute (JRTRI 1999), permissible differential settlement = $0.1\text{--}0.2$ m (damage needing minor retrofit measures).

Severe differential settlement = >0.2 m (damage needing long-term retrofit measures).

It may be noted that Eurocode 8 (1994) and Wu and Prakash (1996) recommend using specified horizontal displacements of the retaining wall for evaluating its seismic performance, while JRTRI suggests the use of vertical differential settlement as the performance criterion which seems reasonable for traffic accessibility and retrofit purposes after the earthquake.

Analysis and Design Issues of Geotechnical Systems: Rigid Walls,

Fig. 19 Free body diagram of forced vibration of a gravity retaining wall retaining saturated backfill soil

Any procedure in the performance-based design of retaining walls should follow these steps:

- Assume a permissible displacement, δ_{per}
- Determine the yield acceleration that corresponds the permissible displacement as

$$a_y = \left(0.087 \frac{V_{max}^2 \alpha_{max}^3}{\delta_{per}} \right)^{1/4} \quad (44)$$

- Having the yield acceleration determined in the previous step, calculate P_{AE} using the M-O method.
- Calculate the wall weight required to limit the wall displacement to the permissible displacement taken in the first step as

$$W = \left[\frac{P_{AE} \cos(\delta + \beta) - P_{AE} \sin(\delta + \beta) \tan \phi_b}{\tan \phi_b - a_y/g} \right] \quad (45)$$

A factor of safety 1.2–1.5 should be applied to the weight of the wall to take into account the probability of exceedance in permissible

displacements of the wall, the importance of the wall, the effects of failure, and the cost of repair.

Analytic Fragility and Limit States [P(EDP|IM)]: Nonlinear Dynamic Procedures

Dimitrios Vamvatsikos

School of Civil Engineering, National Technical University of Athens (N.T.U.A.), Athens, Greece

Introduction

The determination of structural response given the seismic loading is of paramount importance in earthquake engineering. Due to the random nature of earthquakes, it is widely accepted that this is best done in probabilistic rather than deterministic terms. Thus, modern frameworks for performance-based earthquake engineering are based on the evaluation of the distribution of structural response, characterized by one or more engineering demand parameters (EDPs, e.g., peak interstory drift ratio or peak floor acceleration), given the level of a (typically scalar) intensity measure (IM, e.g., peak ground acceleration or first-mode spectral acceleration), used to characterize the earthquake loading (Cornell and Krawinkler 2000). This distribution is symbolized by the corresponding probability distribution function (PDF) of EDP given the IM: $P(EDP|IM)$.

Such results are often employed in tandem with one or more distinct limit or damage states that characterize the performance (or state) of the structure, such as immediate occupancy, life safety, or near collapse. Then, the results of structural analysis can be distilled into the so-called building-level fragility functions associated with the violation of each limit state. Formally, a (building-level) fragility function is the cumulative distribution function of the seismic intensity, in terms of the IM, needed to violate the limit state. A limit state is usually tied to specific threshold capacity (EDP_c) values of one or more EDPs that can be either deterministic (i.e., assumed to be perfectly known) or probabilistic, the latter obviously being the more realistic option. When such values are exceeded, the

limit state is deemed to have been violated. In the case where a limit state is defined via a *single* EDP, e.g., exceedance of 3 % peak interstory drift to define life safety (or worse), the fragility function is essentially the same as the probability function of the seismic demand EDP exceeding the capacity EDP_c given the IM, symbolized as $P(EDP_c < EDP|IM)$.

Fragility can be determined in a variety of ways, using, for example, empirical data from post-earthquake surveys or even expert opinion. For the vast majority of cases, though, computer-intensive analytical options are the most suitable choice. In this direction, recent advances in computer technology have allowed the consideration of nonlinear dynamic analysis as a realistic option. In the following, a number of approaches will be discussed on how to assess the distribution of EDP given IM and determine fragility functions using nonlinear dynamic analysis.

Intensity Measure and Ground Motions

The importance of selecting an efficient and sufficient IM (Luco and Cornell 2007) cannot be understated. An efficient IM will generally be well correlated with the EDPs of choice, thus showing low dispersion of demand given the IM, and subsequently allow the determination of EDP demand or IM capacity statistics using a relatively low number of ground motion records. Sufficiency is defined as the independence of the distribution of EDP given the IM from any other seismological parameters that may characterize the ground motion, e.g., duration, magnitude, spectral shape, or the presence of a pulse indicative of near-source forward directivity. A sufficient IM essentially captures all seismological information needed to determine the effect of a ground motion record on the structure being investigated (see also Jalayer et al. 2012). In other words, it frees the analyst from having to be careful regarding the selection (sampling) of ground motion records, as one only needs to match the required level of IM and no other seismological parameter.

A sufficient IM is essentially the premise of scaling, where the acceleration values of a ground motion time history are uniformly multiplied by a constant to reach the intensity needed. Still, it can be safely assumed that no IM for which a seismic hazard curve can be practically estimated (i.e., those for which ground motion prediction equations currently exist) will ever be 100 % sufficient for all sites and structures. Thus, excessive scaling may introduce biased estimates of response (Luco and Bazzurro 2007). Still, given the limitations of the catalogue of recorded ground motion records, scaling is often the only method to be used to reach truly high IM values that can force a modern well-designed structure to experience global collapse.

A standard IM choice is the 5 % damped first-mode (pseudo) spectral acceleration $S_a(T_1)$ (Shome et al. 1998; Shome and Cornell 1999). This is generally adequate for first-mode-dominated structures that do not displace far into the nonlinear region, as is the case of most existing brittle or moderately ductile low-/mid-rise buildings. For structures where higher modes become important or modern buildings that exhibit significant ductility, improved IM alternatives should be sought. One particularly attractive option is using $S_{agm}(T_i)$ geometric mean of spectral acceleration values at several periods T_i (Cordova et al. 2000; Vamvatsikos and Cornell 2005; Bianchini et al. 2009) that can largely alleviate the effect of spectral shape, being able to capture both the period elongation characterizing ductile structures and the effect of higher modes. Another option that can offer similar, if not better, sufficiency is the compound IM proposed by Luco and Cornell (2007) based on the combination of inelastic spectral displacement at the first mode and the elastic spectral displacement at the second mode of the structure. Its only disadvantage is the need for using specialized ground motion prediction equations to run seismic hazard analysis, developed according to Tothong and Cornell (2006).

Whenever an IM is not sufficient enough to remove the influence of other seismological parameters, their distribution at each IM level should be properly accounted for by

appropriately selecting ground motion records. Thus, for example, if spectral shape, duration, or any other feature that cannot be accounted for by the IM is deemed to be important, the ground motion records used at different intensities should be chosen to reflect the anticipated distribution of those features given the IM. A prime example of a selection method is the conditional spectrum (CS) by Lin et al. (2013a, b), whereby the distribution of spectral shape, characterized by the parameter epsilon (Baker and Cornell 2006), is taken into account. Furthermore, Bradley (2010) has proposed the generalized conditional intensity measure (GCIM) approach to also incorporate other significant characteristics such as the duration and number of significant cycles of the ground motion. For additional information, see also Iervolino and Cornell (2005) and the comprehensive review of record selection provided by Katsanos et al. (2010).

While undoubtedly useful, ground motion selection is not a panacea. It is a method that is site and structure dependent, thus heavily encumbering or even precluding its use whenever a building portfolio or an entire building class (e.g., mid-rise steel frames of the Western USA) is to be assessed to extract fragility or vulnerability functions. Additionally, the boundaries of the recorded ground motions' catalogue put a limit on what can be actually represented by natural records. Thus, it is often the case that a combination of selection and scaling needs to be employed. Alternatively, one could also employ the results of CS or GCIM methods to create artificial ground motions that display the required characteristics. Still, this is an option that is presently available only for highly proficient analysts, as appropriate algorithms have not appeared in the literature so far.

Alternatively, a good rule for a general use is to utilize strong records that when unscaled can still damage the investigated structure, together with a relatively sufficient IM to allow scaling within reason. For most existing low-/mid-rise structures having low-to-moderate ductility that are not subject to near-field motions, this generally means employing $S_a(T_1)$ together with records having naturally high $S_a(T_1)$ values.

Analytic Fragility and Limit States [P(EDP|IM)]: Nonlinear Dynamic Procedures, Fig. 1

The resulting points of a cloud approach for a 9-story steel frame using $S_d(T_1)$ as the IM and the maximum over all stories peak interstory drift $\theta_{\max}$ as the EDP

For modern ductile structures or non-ductile buildings that are not first-mode dominated (e.g., plan-asymmetric or tall structures) or whenever the site of interest is subject to near-field motions, a strong set of records together with an improved IM (see earlier discussion) should be preferred.

Analysis Strategies

Determination of fragility necessitates a wide-range assessment of structural response at multiple levels of intensity. There are several ways to organize the execution of nonlinear dynamic analyses, mainly differing in the manner of postprocessing and in how they can employ ground motion selection and scaling. The main candidates are three (Jalayer and Cornell 2009): cloud analysis, stripe analysis, and incremental dynamic analysis (IDA).

Of the three, cloud analysis is the least restrictive. Its name is derived from the characteristic cloud of results that appears in the IM versus EDP plane, where each point corresponds to one analysis (see Fig. 1). One can employ any combination of scaling and record set selection. At one end, one can employ only scaling, using a fixed

record set that is scaled to several levels of intensity (typically by multiplying all natural accelerograms by the same scale factor). At the other end, scaling can be completely avoided (if possible, considering catalogue limitations) by using a separate set of natural records for each level of IM (within some tolerance of course). Extracting the P(EDP|IM) information can be done in several ways. One approach is to employ parametric regression, taking care to separately fit the non-collapsing IM-EDP points via a linear regression in logarithmic space. “Infinite EDP” points indicative of collapse should be accounted for using logistic regression (see Shome and Cornell 1999; Jalayer and Cornell 2009). Alternatively, a nonparametric approach can be used, employing, e.g., “running” 16/50/84 percentiles to estimate the median and dispersion of the EDP response at each level of the IM.

Stripe analysis is named after the characteristic stripes of points aligned in distinct rows at different IM levels (Fig. 2). Like cloud analysis, it may involve any number of sets of records, and it also needs to employ at least some scaling to make sure that all runs at a given IM level actually perfectly correspond to the IM level requested, without any tolerance. The importance of this detail is that the distribution of EDP given

Analytic Fragility and Limit States [P(EDP|IM)]: Nonlinear Dynamic Procedures, Fig. 2

Analytic Fragility and Limit States [P(EDP|IM)]: Nonlinear Dynamic Procedures, Fig. 3

The resulting IDA curves for a 9-story steel frame using $S_d(T_1)$ as the IM and the maximum over all stories peak interstory drift $\theta_{\max}$ as the EDP

IM is directly represented at each IM level by the empirical distribution of the EDP results extracted from the pertinent analyses. In other words, any statistical quantity of EDP given the IM (mean, 16/50/84 percentile, standard deviation, etc.) can be estimated directly from the corresponding EDP values without any need for parametric or nonparametric regression, thus considerably simplifying postprocessing.

Incremental dynamic analysis (IDA) is based on scaling and scaling only (Vamvatsikos and Cornell 2002). Its focus is on individual records, each of which is scaled to several levels of intensity, typically until collapse is reached. Although closely related to stripe analysis, its main advantage is that the IM levels of the different records do not need to match. Instead, a fixed number of nonlinear dynamic analyses can be utilized for

Analytic Fragility and Limit States $[P(\text{EDP}|\text{IM})]$: Nonlinear Dynamic Procedures,

Fig. 4 Thirty IDA curves, thirty limit-state capacity points, and the corresponding EDP_c , IM_c PDFs for a 9-story steel frame (From Vamvatsikos 2013)

each record to achieve an accurate yet economical representation of response from elasticity to global dynamic instability. Then, interpolation of the results pertaining to each record is employed to generate continuous IDA curves (Fig. 3), as well as stripes, and subsequently derive the needed $\text{EDP}|\text{IM}$ statistics (Vamvatsikos and Cornell 2004).

In practice, any of the above approaches can be used to derive equivalent results. The distinction may become important only in the sense of scaling versus selecting ground motion records that puts IDA at a potential disadvantage: It has to use the same set of ground motions for all intensity levels, needing a sufficient IM to provide unbiased results. On the other hand, the representation of the $\text{EDP}|\text{IM}$ statistics via continuous IDA curves offers a powerful visual tool for understanding structural performance that can often tip the scales in its favor. In the end, the choice lies with the analyst and his/her understanding of the problem at hand.

As a final remark, it is important to remember that the aforementioned methods can only take into account the record-to-record variability. If other sources of uncertainty need to be incorporated, for example, model parameter variability, then more refined (and complex) approaches should be adopted instead (Liel et al. 2009;

Dolsek 2009; Vamvatsikos and Fragiadakis 2010; Jalayer et al. 2011).

Determination of Fragility

A building-level fragility function is defined as a probability-valued function of the IM that represents the probability of violating a limit state given the IM level. Formally, it may be represented as $P(C < \text{DI}|\text{IM})$, i.e., as the probability of the seismic demand D exceeding the seismic capacity C given the IM. Two alternative yet equivalent formats exist to define the C and D terms, namely, the IM basis and the EDP basis. When a single EDP is used to define the limit state, this dichotomy is best understood by visualizing the first exceedance of the limit state as a single point on each IDA curve, having unique IM and EDP coordinates (Fig. 4).

If we choose to characterize demand and capacity by their IM counterparts, then $P(C < \text{DI}|\text{IM})$ simply becomes the cumulative distribution function (CDF) of the IM-valued capacity, IM_c . Simply plotting the empirical CDF of the IM_c values, as, for example, in Fig. 5, provides us with a ready estimate of the fragility function. By estimating the appropriate statistics (median, IM_{c50} , and standard deviation of the log

Analytic Fragility and Limit States $P(EDP|IM)$: Nonlinear Dynamic Procedures, Fig. 5 The empirical fragility function for exceeding a (deterministic) peak interstory drift of 3 % for the 9-story steel frame versus its lognormal approximation

values, β_{IMc}), one may also represent the results via an analytic lognormal approximation, as shown in Fig. 5, and formally represented by the following expression:

$$P(EDP_c < EDP|IM) = \Phi\left(\frac{\ln IM - \ln IM_{c50}}{\beta_{IMc}}\right). \quad (1)$$

If instead D and C are represented in EDP terms, then they are both potentially random quantities and integration is needed:

$$P(EDP_c < EDP|IM) = \int_0^{+\infty} P(EDP_c < EDP) P(EDP|IM) dIM. \quad (2)$$

The first term of the integrant is essentially the complementary cumulative distribution function (CCDF) of EDP_c , and the second is the probability distribution function (PDF) of EDP given the IM. Despite the apparent complexity of this approach, it is often the preferred method for estimating fragility (although not necessarily for representing it). This is best understood by considering the simpler case where the EDP capacity

is deterministic, i.e., we presume to perfectly know the value of EDP that causes violation of the limit state. Then, the capacity points of Fig. 4 align themselves into a single vertical line that intersects all IDA curves at the limiting (single) EDP_c value, meaning that all the dispersion in the fragility function (or the IM_c values, equivalently) originates from the records themselves. Inversely, if one wants to introduce the (typically considerable) uncertainty in EDP_c , he/she had best go through the EDP route; otherwise, it is not possible to obtain the inflated β_{IMc} dispersion of Eq. 1. Regardless of the route taken, though, the end result can always be represented in terms of the lognormal function parameters IM_{c50} and β_{IMc} of Eq. 1.

Summary

A key ingredient of modern frameworks for performance-based earthquake engineering is the assessment of the distribution of structural demand given the seismic intensity. Expressed as the probability of exceeding specific levels of the structural response indicative of defined limit states, this is also known as fragility. Recent advances in computer technology have allowed

the use of resource-intensive nonlinear dynamic analysis as the tool of choice for analytically estimating such fragility functions. For practically implementing such an assessment, several strategies exist on how to select and/or modify ground motion records and apply them to a structural model at several levels of intensity. Clouds, stripes, and incremental dynamic analysis curves, each characterized by the appearance of the corresponding results in the response versus intensity space, are among the most prominent techniques. Despite their superficial differences, they may all achieve the same fidelity in their results, practically differing only in the ease of postprocessing and interpretation. In all cases, parameterization by the (typically scalar) intensity measure means that considerable attention should be paid to its selection, as well as the selection of the ground motions, to ensure the unbiasedness of the estimates.

Fragility analysis; Fragility curve; Limit state; Nonlinear static procedure; Pushover analysis; SDOF model; Seismic demand; Target displacement; Uncertainty

Introduction

Nonlinear static (pushover-based) procedures were initially developed for the seismic performance assessment of structures (e.g., Saiidi and Sozen 1981; Fajfar and Fischinger 1988; Paret et al. 1996; Chopra and Goel 2002) and later on used also for the fragility analysis (e.g., Fragiadakis and Vamvatsikos 2010; Barbato et al. 2010; Dolšek 2012; Jalayer et al. 2011; Rota et al. 2014; Kosič et al. 2014). For example, Jalayer et al. (2011) proposed the use of Bayesian method for calculating fragility curve of the reinforced concrete frame. Rota et al. (2014)

adopted logic tree approach for evaluating the effects of modelling uncertainties on the fragility curves of masonry buildings. Alternatively, the impact of the modelling uncertainties on the fragility curve can be simulated by utilizing the so-called probabilistic SDOF model (Kosič et al. 2014). The advantage of pushover analyses in comparison with nonlinear response history analysis lies in the former's simplicity, since the results of pushover analysis are very intuitive. This makes pushover-based methods attractive for practical applications. On the other hand, they are based on several assumptions. Thus, the analyst should have good background knowledge in order to be able to adequately interpret results obtained by using pushover-based methods. However, many studies have shown that, in the case of simple bridges and buildings up to around eight stories high, the mean/median response can be sufficiently accurately predicted by means of conventional pushover analysis. In the case of more complicated structures, the analyst should think about taking into account, at least approximately, torsional effects and the so-called higher mode effects (e.g., Reyes and Chopra 2011; Kreslin and Fajfar 2012). Reyes and Chopra (2011) and Kreslin and Fajfar (2012) used linear elastic analysis in estimating higher mode contributions seismic demands. If the target displacement is obtained by nonlinear response history analysis utilizing the single-degree-of-freedom (SDOF) model, then it is possible to consider the different system failure modes obtained from the pushover analyses (Brozovič and Dolšek 2014). In this case, the failure-based SDOF models are used in addition to the modal-based SDOF model associated with the first model.

It should be noted that the main objective of this entry is to introduce the use of conventional pushover-based method for fragility analysis, taking into account the randomness of ground motion and the epistemic (modeling) uncertainty. Thus, not all issues associated with pushover-based methods are precisely addressed.

The entry has been organized into three sub-entries. The theoretical background for the prediction of the parameters of SDOF models is first described. This subentry is subdivided into two

parts. The transformation of the equations of motion to a conventional equation of motion of a SDOF model is presented in the first part, while in the second part, the procedure to determine the parameters of the SDOF model using pushover analysis is described. The first subentry provides an insight into the SDOF model, which represents a key link between the pushover analysis and seismic demand. Quite precise instructions are given on how to determine a SDOF model which can be used to assess the seismic demand by nonlinear dynamic analysis. The first subentry is followed by an overview of the different types of pushover analysis and the limit states. Some variants of pushover analyses are only mentioned, since it is not the aim of this entry to provide an insight into different types of pushover analysis. In the final subentry, pushover-based fragility analysis is explained with emphasis on the step-by-step procedure, which is also demonstrated by means of an example of fragility analysis for a four-story reinforced concrete frame building. The EDP-based and IM-based formulations of the fragility function are introduced. This is followed by explaining three procedures for the estimation of the fragility parameters using pushover-based methods. Finally, the most comprehensive procedure, which takes into account the ground-motion randomness and modeling uncertainty, is demonstrated by explaining each step of the pushover-based fragility analysis.

The Theoretical Background for Predicting Parameters of the SDOF Model

The main objective of this derivation is to introduce the theoretical background for the determination of the parameters of the SDOF model, which is one of the key components of the pushover-based methods. The advantage of the SDOF model is its simplicity. Thus, it can be used to determine the seismic demand based on nonlinear response history analyses. However, it is important to understand the theoretical limitations of such approach.

Transformation of Equations of Motion to a Conventional Equation of a Single-Degree-of-Freedom Model

The seismic response of structures can, in general, be described by the equation of motion

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{C}\dot{\mathbf{U}} + \mathbf{K}\mathbf{U} = -\mathbf{M}\ddot{\mathbf{U}}_g \quad (1)$$

where the first, second, and third parts of the equation on the left-hand side represent, respectively, the vectors of the inertial, damping, and resisting forces. The sum of these forces should be in equilibrium with external load, which, in the case of an earthquake, is expressed by the product of the mass matrix $\mathbf{M}$ and the vector of the ground acceleration $\ddot{\mathbf{U}}_g$. Equation 1 is derived for the simulation of the seismic response of a structure relative to the ground. Thus, the displacements $\mathbf{U}$, velocities $\dot{\mathbf{U}}$, and accelerations $\ddot{\mathbf{U}}$ are vectors which are expressed relative to the ground. The kinematic quantities are, in general, simulated at all joints of the finite elements which form the structure. The matrix $\mathbf{C}$ is a damping matrix, which is often modeled in proportion to the mass matrix and/or the stiffness matrix $\mathbf{K}$. It should be noted that all kinematic quantities are functions of time. In the case of the nonlinear response of a structure, the stiffness matrix and, in some cases, also the damping matrix depend on the history of the structure's deformations.

In order to achieve brevity of the derivation, it is assumed that the building structure is symmetric in plan. The problem therefore simplifies to the planar case. It is further assumed that the seismic response of the building can be described just by the horizontal displacements at each story level. The external load of Eq. 1 simplifies as follows:

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{C}\dot{\mathbf{U}} + \mathbf{K}\mathbf{U} = -\mathbf{M}\mathbf{1}\ddot{u}_g \quad (2)$$

where $\mathbf{1}$ is a vector with ones, and $\ddot{u}_g$ is the ground acceleration. It should be noted that the vector of the resisting forces,

$$\mathbf{F} = \mathbf{K}\mathbf{U} \quad (3)$$

which are function of time, can now be understood as the external, equivalent, static forces

which produce a vector $\mathbf{U}$ of displacements at any individual floor level, at any instant in time. Despite simplifications, Eq. 2 is a system of n -dependent nonhomogenous second-order differential equations with nonlinear coefficients, where n stands for the number of stories of the building structure. Several methods exist for the solution of this equation at any instant in time, but there are also several reasons to further simplification of the problem.

For example, all nonlinear structural models are just an approximation of the realistic seismic response of a structure. The majority of current structural models are capable of simulating several of the failure modes that can be observed in realistic structures. From this point of view, the question arises as to whether it is justified to treat the whole system as dynamic, if the model used to represent a building structure is already a proxy of reality. Furthermore, although the solution of the equation of motion will provide exact results from the theoretical point of view, the seismic loading is not known in advance. Thus, the selection of inappropriate ground motions could have a greater impact on the results than the selected method of analysis. Finally, solving system of equations of motion is extremely time demanding and, in the case of complex systems, also related to poor convergence of the numerical results obtained. These are just some reasons that it is often not practical to use response history analysis in order to simulate the seismic response of a structure. Therefore, Eq. 2 is often further simplified.

The solution of Eq. 2 would be significantly easier if the motion of the structure could be described with sufficient accuracy by reducing the number of differential equations to just one, e.g., in the case of building structures, by simulating just the top (roof) displacement. From the theoretical point of view, such a simplification can be achieved by assuming a displacement vector $\mathbf{U}$ in the following form:

$$\mathbf{U} = \Psi u_t \quad (4)$$

where Ψ is a displacement vector that is independent of time and is normalized to a top

displacement equal to 1, and u_t is the top displacement, which is a function of time. Based on such an assumption, it becomes clear that a multi-degree-of-freedom (MDOF) model of a structure can be transformed into a single-degree-of-freedom (SDOF) model. This is achieved by substituting all the kinematic quantities in the form of Eq. 4 and pre-multiplying Eq. 2 by the vector Ψ^T :

$$\Psi^T \mathbf{M} \Psi \ddot{u}_t + \Psi^T \mathbf{C} \Psi \dot{u}_t + \Psi^T \mathbf{K} \Psi u_t = -\Psi^T \mathbf{M} \mathbf{1} \ddot{u}_g \quad (5)$$

Equation 5 can be rearranged into the following form:

$$m_\psi \ddot{u}_t + c_\psi \dot{u}_t + k_\psi u_t = -m_* \ddot{u}_g \quad (6)$$

by realizing that the results of the multiplication of the matrices (Eq. 5) are scalars:

$$\begin{aligned} m_\psi &= \Psi^T \mathbf{M} \Psi \\ c_\psi &= \Psi^T \mathbf{C} \Psi \\ k_\psi &= \Psi^T \mathbf{K} \Psi \end{aligned} \quad (7)$$

$$m_* = \Psi^T \mathbf{M} \mathbf{1} \quad (7a)$$

By introducing Eq. 6, it is clear that the system of n -dependent differential equation has been simplified to just one equation of motion, where the unknown quantities are the displacement, velocity, and acceleration at the top of the building. However, it still does not have the form of the conventional equation of motion, since $m_* \neq m_\psi$. In order to make Eq. 6 equivalent to the conventional equation of motion, a so-called transformation factor, which relates the top displacement of the structure to the displacement of the SDOF model, needs to be defined as follows:

$$\Gamma = \frac{m_*}{m_\psi} = \frac{\Psi^T \mathbf{M} \mathbf{1}}{\Psi^T \mathbf{M} \Psi} \quad (8)$$

and the kinematic quantities of the SDOF model as

$$u_* = \frac{u_t}{\Gamma}, \quad \dot{u}_* = \frac{\dot{u}_t}{\Gamma}, \quad \ddot{u}_* = \frac{\ddot{u}_t}{\Gamma} \quad (9)$$

Equation 6 can now be transformed into the conventional equation of motion of the SDOF model by taking into account Eqs. 8 and 9:

$$m_* \ddot{u}_* + c_* \dot{u}_* + k_* u_* = -m_* \ddot{u}_g \quad (10)$$

where

$$c_* = \Gamma c_\psi \quad (11)$$

and

$$k_* = \Gamma k_\psi \quad (11a)$$

Determination of the Parameters of the SDOF Model Using Pushover Analysis

There are no exact instructions as to how to determine the parameters of the SDOF model since the mass m_* , the damping c_* , and the stiffness k_* all depend on the assumed displacement shape. In order to obtain a practical solution to Eq. 10, the analyst has to determine the force-displacement relationship of the SDOF model taking into account certain hysteretic rules, which are often assumed to be similar to those used for the structural components. However, the displacement of the SDOF model can be simply determined according to Eq. 9. Some further explanation is needed in order to be able to better understand the background for the determination of the forces of the SDOF model from the pushover curve. In general, the product of the stiffness k_* and u_* represents a force in the spring of the SDOF model:

$$F_* = k_* u_* \quad (12)$$

which should be expressed in a different form by taking into account Eqs. 11a and 9:

$$F_* = k_\psi u_t \quad (13)$$

Equation 13 can be further transformed by substituting k_ψ using Eq. 7 and with consideration of Eqs. 3 and 4:

$$F_* = \Psi^T \mathbf{F} \quad (14)$$

It should be noted that the force-displacement relationship of the SDOF model is, in general, nonlinear due to the nonlinear response of the structure. Thus, there is no exact answer as to which is the most appropriate shape of the normalized displacement vector Ψ or which are the most appropriate lateral forces $\mathbf{F}$. If it is assumed that the structure oscillates just in one given mode shape, then $\Psi = \Phi$. If it is further assumed that the mode shape Φ does not change significantly with increasing damage to the structure and that the damping does not affect the shape of the buildings' oscillation, then it can be shown, by analogy to the modal analysis, that the shape of the equivalent static forces which causes lateral displacements that are equivalent to the mode shape can be expressed as follows:

$$\mathbf{F} = \mathbf{M} \Phi \quad (15)$$

Substituting Eq. 15 into Eq. 14 and realizing that in such a case $\Psi = \Phi$, it can be shown that

$$F_* = \Phi^T \mathbf{M} \Phi \quad (16)$$

Multiplying and dividing Eq. 16 by $m_* = \Psi^T \mathbf{M} \mathbf{1}$ and taking into account Eq. 8 produces the following result:

$$F_* = \frac{\Phi^T \mathbf{M} \mathbf{1}}{\Gamma} \quad (17)$$

Eq. 18 can be further simplified by realizing that $\mathbf{F}^T = \Phi^T \mathbf{M}$:

$$F_* = \frac{\mathbf{F}^T \mathbf{1}}{\Gamma} = \frac{F_b}{\Gamma} \quad (18)$$

where F_b is the so-called base shear, i.e., the sum of the lateral forces $\mathbf{F}$. The force-displacement relationship of the SDOF model is thus obtained simply by dividing the quantities at the structural level by the so-called transformation factor. However, it should be emphasized that Eq. 18 may not be sufficiently accurate in the case when the pushover curve is based on a higher mode shape. Equation 9 can be used, together with Eqs. 14 or 18, to determine the

force-displacement $F_* - u_*$ relationship of the SDOF on the basis of the pushover curve.

It is often useful to know the period of the SDOF model, which can be obtained by analyzing Eq. 10. It is well known that the radial frequency of an oscillating body is

$$\omega_* = \sqrt{\frac{k_*}{m_*}} = \frac{2\pi}{T_*} \quad (19)$$

whence it follows that

$$T_* = 2\pi \sqrt{\frac{m_*}{k_*}} \quad (20)$$

The stiffness of the SDOF model can be expressed by means of Eq. 12. The period of the SDOF model thus equals

$$T_* = 2\pi \sqrt{\frac{m_* u_*}{F_*}} \quad (21)$$

In order to solve Eq. 10, it is necessary to define the damping model c_* . The so-called Rayleigh damping model is often assumed at the level of the structure. In this case, the damping matrix is expressed as a linear combination of the mass and stiffness matrices:

$$\mathbf{C} = \alpha \mathbf{M} + \beta \mathbf{K} \quad (22)$$

where α and β are constant values. The question arises as to how to relate the damping model at the structural level to the damping model for the SDOF model. Starting from Eq. 11 and taking into account Eq. 7 for c_ψ as well as Eq. 22, it can be shown that

$$\begin{aligned} c_* &= \Gamma c_\psi = \Gamma \Psi^T \mathbf{C} \Psi = \Gamma \Psi^T (\alpha \mathbf{M} + \beta \mathbf{K}) \Psi = \\ &= \Gamma (\alpha \Psi^T \mathbf{M} \Psi + \beta \Psi^T \mathbf{K} \Psi) = \\ &= \alpha \Gamma m_\psi + \beta \Gamma k_\psi \end{aligned} \quad (23)$$

Substituting Eqs. 8 and 11 into Eq. 23, the following equation is obtained:

$$c_* = \alpha m_* + \beta k_* \quad (24)$$

whence it can be shown that the same damping constants α and β of the SDOF model are equal to that assumed for the response history analysis of the entire structure. The damping constants α and β , or only one of these constants, if damping is proportional to the mass or stiffness matrix only, are often determined by assuming a certain ratio of critical damping. Describing the relationship between the damping constants and the ratio of critical damping is, however, outside the scope of this derivation.

Equation 10 can be solved by numerical integration which is implemented in conventional software for response history analysis. However, the solution depends, in general, on the ground motion and assumptions adopted for the determination of the parameters of the SDOF model, i.e., the mass m_* , the damping model, the force-displacement relationship $F_* - u_*$, and the hysteretic rules.

In the simplest and the most commonly used approach, the parameters of the SDOF model are determined by performing pushover analysis taking into account invariant distribution of the lateral forces. In this case, the procedure for the determination of the parameters of the SDOF model can be decomposed into the following steps:

1. Define the distribution of the lateral forces $\mathbf{F}$ for the pushover analysis.
2. Perform the pushover analysis. This results in the relationship between the force vector $\mathbf{F}$ and the displacement vector $\mathbf{D}$ from elastic range to the collapse of the structure. The corresponding base shear F_b and the top displacement u_t form the so-called pushover curve.
3. Assume the shape of the normalized displacement vector Ψ .
4. Idealize the pushover curve $F_b - u_t$ using a bilinear or multi-linear shape or the shape of any other curve which can be used to simulate the $F_* - u_*$ force-displacement relationship of the SDOF model.
5. Compute the $F_* - u_*$ force-displacement relationship of the SDOF model. The force F_* at the characteristic points of the idealized

pushover curve can be obtained, in the case of the SDOF model, according to Eq. 14. In the case when the distribution of displacement vector $\mathbf{D}$ is more or less constant for all levels of damage, then the forces F_* can be determined by Eq. 18.

6. Assume hysteretic behavior of the SDOF model.
7. Compute the mass m_* of the SDOF model according to Eq. 7.
8. Compute the damping constants α and/or β based on the assumed damping model and the ratio of critical damping.

Pushover Analysis and Limit States

Pushover analysis is a kind of nonlinear static analysis which aims at determining the relationship between the lateral forces and the engineering demand parameters (EDPs) for all performance levels of a structure. The results of pushover analysis are very intuitive, which makes it attractive for practical applications. It is clear that the relationship between the forces and the deformations are linearly elastic until damage occurs to the first element. Beyond this level, an increment of lateral forces causes a greater increment in the deformations in comparison with that observed in the case of linear elastic analysis, since the stiffness of the structure is reduced due to the damage which has occurred to some of the elements. When the deformations reach a certain level, the maximum strength of the structure is reached. From here on, the strength of the structure decreases due to the softening of the material (e.g., see Fig. 2) or due to second-order effects, if they are considered in the analysis. In less general case, when the softening of material and second-order effects is not taken into account, the pushover curve becomes a straight line once a plastic mechanism forms.

The strength and deformation capacity, the available ductility, and the system failure mode represent the global results of the pushover analysis, which should always be checked in the case when seismic performance assessment of structure is based on a nonlinear analysis method. The

results of a pushover analysis are usually presented in the form of a pushover curve, which represents a relationship between the base shear and top (roof) displacement of the investigated structure (e.g., see Fig. 2). The pushover curve is, in fact, a characteristic of the structure. However, it depends on the type of pushover analysis used.

The pushover analysis becomes an approximate analysis method if it is used for the prediction of expected seismic performance of a structure (e.g., Saiidi and Sozen 1981; Fajfar and Fischinger 1988; Fajfar 2000). In this case, it is important that the structural model implicitly accounts for the cyclic deterioration. However, the results of pushover analysis are used for the definition of the SDOF model, which represents a link between the seismic action and the seismic demand.

The seismic demand at the level of the SDOF model can be obtained by means of numerous procedures. Once the displacement at the level of the SDOF model has been obtained, it can be transformed to the selected EDP at the structural level. Since several phenomena associated with the response of a structure during an earthquake are neglected in pushover-based methods, it is clear that the results of such simplified procedure are approximate also from the theoretical point of view. Due to the approximate nature of pushover-based procedures, many types of pushover analysis have been developed in recent decades. Some of them are briefly described below.

Types of Pushover Analysis

Conventional pushover analysis (e.g., Saiidi and Sozen 1981; Fajfar and Fischinger 1988) is based on an invariant distribution of the lateral forces. The shape of the lateral forces is therefore independent of deformations, whereas the shape of the deformations is dependent on the level of structural damage. This is the most common type of pushover analysis, which is recommended by some guidelines and building codes (e.g., FEMA 356, Eurocode 8). It is usually prescribed that pushover analysis should be performed for at least two vertical distributions of the lateral loads

in order to assess the range of EDPs that might occur during actual dynamic response. Eurocode 8 suggests the use of the so-called uniform and modal load patterns, which are, respectively, proportional to the story masses and the lateral forces from the elastic analysis. According to FEMA 356, two patterns have to be selected from two groups. The first load pattern should be consistent with the modal pattern, whereas a second pattern can be based on a uniform load pattern or on an adaptive load distribution which accounts for the redistribution of the lateral loads, taking into account the properties of the yielded structure. Due to the simplicity of conventional pushover analysis, even more than two pushover analyses can be easily performed. For example, an iterative pushover-based procedure (IPP) (Celarec and Dolšek 2013) involving model adaptation was recently introduced, which aims at improving the capability of simulations based on simplified nonlinear models. It was shown that the IPP can be used to approximately simulate the shear failure of columns (Celarec and Dolšek 2013; Kosič et al. 2014), although simplified nonlinear models are not capable of direct simulation of such effects.

Adaptive pushover analysis is an alternative to conventional pushover analysis. In force-based adaptive pushover analysis, the load vectors are gradually updated due to the damage occurring to the structure, which affects the mode shapes. One of the first procedures for the adaptive lateral load for pushover analysis was proposed by Bracci et al. (1997). Many different procedures for force-based adaptive pushover analysis followed. Most approaches involve response spectrum analysis which is performed for the different modal characters of the structure which are associated with selected stages of the pushover analysis. However, Aydinoglu (2003) has argued that the load patterns should be based on an inelastic rather than an elastic response spectrum. It was soon realized that force-based adaptive pushover analysis offers only a relatively minor advantage in comparison with conventional pushover analysis. As a result of such an observation, a displacement-based adaptive pushover procedure was proposed (Antoniou and Pinho 2004), which,

however, did not provide significantly improved prediction in comparison to the force-based algorithms that are used for adaptive pushover analysis.

Conventional or adaptive pushover analysis provides a single pushover curve, which can be used in conjunction with the SDOF model to obtain the expected values of EDPs. For some types of buildings and EDPs, such a simulation of the seismic response of a structure provides sufficiently accurate results. However, the analyst has to be careful when interpreting the results of the seismic performance assessment of a structure on the basis of one pushover curve, since it is not possible to assess all types of EDPs on the basis of single pushover analysis. In general, the dynamic response of a structure is far more complex, especially if it suffers significant damage. In general, several system failure modes can be observed due to the randomness of ground motions. Additionally, in the case of taller buildings, several modes can significantly contribute to the results. On the other hand, mode shapes depend on the scale of inflicted damage, which gradually increases during a strong earthquake. Thus, the maximum values of EDPs do not appear at the same instant in time. Furthermore, the impact of mode shapes varies with respect to the EDPs. For example, the higher mode effects can be significant for the prediction of story drifts and for the internal forces in the upper parts of taller buildings. Much effort has been expended in order to try to approximately account for the so-called effect of higher modes. One of the first attempts in this direction has been made by Paret et al. (1996), who performed several pushover analyses using a lateral load pattern based on different elastic mode shapes. A theoretical basis for the modal pushover analysis procedure for estimating the seismic demand for buildings was introduced by Chopra and Goel (2002). The method involves several pushover analysis and corresponding modal-based SDOF models, whereas the overall response is obtained by combining the results of all considered modes. Recently, a general pushover analysis was introduced (Sucuoğlu and Günay 2011). It is based on several pushover analyses, which are performed

on the basis of the lateral forces obtained as a combination of the modal forces. It was also shown that the so-called higher system failure modes can significantly contribute to the response of taller buildings. Brozovič and Dolšek (2014) have shown that system failure modes observed due to the randomness of ground motion can be sufficiently accounted for by the envelope-based pushover analysis procedure, which is based on several pushover analyses and the use of failure-based SDOF models. The failure-based SDOF models utilize the displacement vectors corresponding to the system failure modes that are observed from pushover analyses in the case of second or higher modes. This significantly improves the prediction of the intensity causing a designated limit state, if the structure is sensitive to the effects of higher modes.

Definition of Limit States

As already mentioned above, pushover analysis is the simplest nonlinear analysis method, which has been included in several guidelines and standards for seismic performance assessment and the retrofitting of buildings. The results of pushover analysis can be used, in conjunction with the target displacement for a given seismic action, to check whether the structural performance satisfies the defined performance objectives. For this purpose, building codes provide limit states at the component or structural level. Eurocode 8-3 (CEN 2005) utilizes the following limit states: damage limitation (DL), significant damage (SD), and near collapse (NC). These limit states are explicitly defined at the component level, whereas definitions at the structural level are only descriptive. For example, it is prescribed that the near-collapse limit state at the structural level is attained when a structure is heavily damaged, with some residual lateral strength and stiffness, but is still capable of sustaining vertical loads and aftershocks of moderate intensity. However, moderate permanent drifts are present, and it is not likely, from the economic point of view, that repair of the building could be justified. Note that the NC limit state is often defined at the global level, i.e., when the strength in the post-capping range of pushover curve decreases for 20 %.

Each country can prescribe return periods of the design seismic action associated with these limit states. By default, it is assumed that appropriate levels of protection are achieved when the structural performance for the DL, SD, and NC limit states is checked for seismic actions corresponding to return periods of 225, 475, and 2475 years, respectively. The prestandard for the seismic rehabilitation of buildings FEMA 356 (2000), which was issued a few years before the Eurocode 8-3, is based on similar metrics for checking the target building performance. The basic structural performance levels of a building are immediate occupancy (IO), life safety (LS), and collapse prevention (CP). FEMA 356 states that building performance is a combination of the performance of both the structural and the nonstructural components. The description of performance levels (i.e., limit states), which are discrete damage states selected from among the infinite spectrum of possible damage states that buildings could experience during an earthquake, consists of estimates rather than precise predictions (FEMA 2000).

According to the brief overview of limit states provided in some standards, it is clear that there are many different definitions of them. In general, each limit state is associated with a certain degree of damage. However, there are some restrictions regarding the definition of limit states on the basis of pushover analysis. For example, the pushover analysis is not able to explicitly simulate cycling deterioration. Thus, in the case of pushover analysis, limit states cannot be dependent on the level of cyclic deterioration. Since damage models are often defined by story drifts or the rotations in plastic hinges, such a limitation of pushover analysis, associated with an inability to simulate cycling deterioration, is not critical, provided that the nonlinear model used for pushover analysis implicitly accounts for cyclic deterioration of the structural components. In the case of nonstructural components, it is common to define a limit state by the level of story acceleration, which is not explicitly simulated by pushover analysis. A simplified model for story acceleration is therefore also required.

Although there are no critical restrictions for the definition of limit states in the case when seismic demand is obtained by the pushover-based method, it should be realized that the accuracy of pushover-based methods is limited. The analyst should therefore be careful when checking the limit states, especially in the case when target performance is defined at the component level. It is thus recommended that the limit states should be defined at the global and structural levels, taking into account the global parameters obtained from the pushover curve. Even in this case, it is recommended that the structural damage associated with such defined limit states should be checked, since it is possible that a flexible structure has not suffered significant damage even though the corresponding point on the pushover curve is beyond the post-capping point. Such performance can be observed in the case of flexible frames, where the P- Δ effect has a quite significant impact on structural performance.

Pushover-Based Seismic Fragility Analysis

The result of fragility analysis is the fragility function, which represents the probability that an engineering demand parameter (EDP) will exceed a certain limit-state value edp given an intensity $IM = im$. In the simplest case, it is assumed that the seismic fragility function is based on a lognormal distribution function:

$$P(EDP > edp | IM = im) = 1 - \Phi\left(\frac{\ln edp - \ln \mu_{edp}}{\sigma_{\ln edp}}\right) \quad (25)$$

where $\Phi\left(\frac{\ln edp - \ln \mu_{edp}}{\sigma_{\ln edp}}\right)$ represents the standard normal distribution function, μ_{edp} is the median value of the EDP given the intensity im , and $\sigma_{\ln edp}$ is the standard deviation of the natural logarithms of the EDP given that $IM = im$. The above definition is suitable when the limit state is based on a threshold value of an engineering

demand parameter. In the case of an IM-based definition of a limit state, which is common for the collapse limit state, the fragility function can be defined as follows:

$$P(LS | IM = im) = \Phi\left(\frac{\ln im - \ln \mu_{imLS}}{\sigma_{\ln imLS}}\right) \quad (26)$$

where $P(LS | IM = im)$ is the probability of exceeding the limit state LS if the intensity measure assumes a value equal to im , μ_{imLS} is the median limit-state intensity, and $\sigma_{\ln imLS}$ is the corresponding standard deviation of the natural logarithms. The fragility function is therefore defined by two parameters, the median value μ_{edp} or μ_{imLS} and the corresponding standard deviation $\sigma_{\ln edp}$ or $\sigma_{\ln imLS}$. Many different procedures for the estimation of these parameters based on pushover analysis have been developed. It should also be noted that many different procedures for fragility analysis exist. Some of them can also be used on the basis of seismic performance assessment utilizing pushover analysis (e.g., Jalayer et al. 2011; Rota et al. 2014).

The accuracy of determination of the fragility parameters (μ , $\sigma_{\ln}$) depends on the method for seismic performance assessment of a structure and the level of the simulations, which accounts for the effect of uncertainty.

Deterministic Approach for Assessing the Parameters of the Fragility Function

In the simplest case, the effects of uncertainty can be assumed by the default values of $\sigma_{\ln}$. Consequently, the deterministic seismic performance of a structure can be used. This enables the use of analytical models for the determination of the target displacement. Parametric studies have shown that the $\sigma_{\ln imLS}$ depends on the limit state and the type of seismic intensity measure. If the intensities causing collapse are assessed by the spectral acceleration corresponding to the first vibration period, the $\sigma_{\ln imLS}$ is in the interval between 0.3 and 0.5 (Lazar and Dolšek 2014). The $\sigma_{\ln imLS}$ increases with respect to the period of structure if it is assessed on the basis of peak ground acceleration. It varies between 0.5 and

0.75. The value of $\sigma_{\ln imLS}$ can additionally increase if epistemic uncertainties are considered in addition to the record-to-record randomness.

In Europe, the most commonly used approach for the determination of expected seismic response based on pushover analysis is the N2 method (e.g., Fajfar 2000), which has been implemented in Eurocode 8 (CEN 2004), whereas the so-called coefficient method is used in the United States (e.g., FEMA 356 (2000)). According to Eurocode 8 and FEMA 356, the target displacement (d_t and δ_t), respectively, can be determined as follows:

$$d_t = \Gamma \cdot \frac{\mu(q_u, T^*, T_C)}{q_u} \cdot S_e(T^*) \frac{T^{*2}}{4\pi^2}, \quad (27)$$

$$\delta_t = C_0 \cdot C_1(R, T_S, T_e) C_2 C_3 \cdot S_a(T_e) \frac{T_e^2}{4\pi^2}, \quad (28)$$

where the parameters Γ and C_0 have the same meaning, i.e., they are the so-called transformation or modification factors which relate the spectral displacement of an equivalent SDOF model to the roof displacement of the MDOF model. For the experienced reader, it is also trivial that the last parts of Eqs. 27 and 28 represent the elastic spectral displacement S_{de} , whereas the middle part of Eqs. 27 and 28 corresponds to the so-called inelastic displacement ratio C (e.g., Miranda 2000), which depends on many parameters, such as the ground motion type, the hysteretic behavior, the force-displacement relationship, the masses, damping, and others. For reasons of simplicity, formulas for the determination of the inelastic displacement ratio have been introduced based on the results of parametric studies. For example, in Eurocode 8, the simplified $R - \mu - T$ relationship proposed by Fajfar (2000) is used to define the inelastic displacement ratio, whereas in FEMA 356 (2000), two additional parameters are used to define the inelastic displacement ratio, i.e., the parameter C_2 , which represents the effect of a pinched hysteretic shape, stiffness degradation, and strength deterioration on maximum displacement, and the parameter C_3 , which represents the increased displacement due to dynamic P- Δ effects. Note that the meaning of

all the variables in Eqs. 27 and 28 is described in the corresponding references (CEN 2004; FEMA 2000).

Consideration of Ground-Motion Randomness in Estimation of Parameters of Fragility Function

The first level of simulations involves consideration of the effect of ground-motion randomness. In general, the target displacement according to this approach is based on nonlinear dynamic analysis of the SDOF model. The analyst should therefore select an appropriate set of ground motions and define the SDOF model, which could be used for nonlinear dynamic analysis as previously described in this entry. The results of such analyses are samples of EDP values given the different values of the intensities or the sample of limit-state intensities, which could be used to estimate the parameters of the fragility function. Some alternatives exist which can be used in order to avoid the use of nonlinear dynamic analysis at the level of the SDOF model. Vamvatsikos and Cornell (2006) developed the SPO2IDA software tool, which is capable of recreating the seismic behavior of a single-degree-of-freedom (SDOF) model with a quadri-linear force-displacement relationship. They performed a parametric study by suitably varying the five parameters of the force-displacement relationship, which are negative and nonnegative hardening, the residual plateau, ductility at the beginning of strength degradation, and ductility at collapse. Based on the results of the parametric study, regression analysis was used to define each segment of the approximate 16th, 50th, and 84th fractile IDA curves. Although SPO2IDA is a useful software tool, it is not easy to extend its applicability, since a new regression analysis is required if the seismic response parameters are to be computed for additional ground motion records. More recently, Peruš et al. (2013) introduced a web-based methodology for the prediction of approximate IDA curves, which consists of two independent processes. The result of the first process is a response database of the single-degree-of-freedom model, whereas the second process involves the prediction of approximate

IDA curves from the response database by using n -dimensional linear interpolation. Such an approach makes possible user-friendly prediction of the seismic response parameters with high accuracy. In order to demonstrate the capabilities of the proposed methodology, a web application for the prediction of the approximate 16th, 50th, and 84th fractile response of a reinforced concrete structure was developed (<http://ice4risk.slo-projekt.info/WIDA/>). Note that web-based methodology for the prediction of the approximate IDA curves estimates an error of the predicted IDA curves of a SDOF model.

Consideration of Ground-Motion Randomness and Epistemic Uncertainty in Estimation of Parameters of Fragility Function

In a general case, fragility parameters should be based on simulations which take into account the effects of ground-motion randomness and the other knowledge-based sources of uncertainty, such as physical uncertainties, modeling uncertainties, human errors, uncertainties associated with the knowledge level about the structure, and others. In order to account for knowledge-based uncertainties, the simulations can be performed at the level of a MDOF model (e.g., Fragiadakis and Vamvatsikos 2010; Dolšek 2012) or a SDOF model (Kosič et al. 2014). Many different simulation methods can be used to perform pushover analysis with consideration of knowledge-based uncertainties (e.g., Barbato et al. 2010; Jalayer et al. 2011). It is convenient and straightforward to utilize Monte Carlo simulation with Latin hypercube sampling (e.g., Fragiadakis and Vamvatsikos 2010; Dolšek 2012). The LHS technique uses stratification of the probability distribution function of the random variables X_i and consequently requires significantly fewer simulations in comparison with the ordinary type of Monte Carlo simulation. In general, two steps are needed to determine the sample of random variables, which are directly applied in the structural model. First, each random variable is sampled by inverse method using equidistant points between sample probabilities. If the random variables are correlated, the sample

should be generated in such a way that the correlation structure between the random variables is simulated in the best possible manner. This represents the second step in the process of the determination of the sample of random variables. The problem can be successfully solved by the stochastic optimization method called simulated annealing. More details are available elsewhere (e.g., Dolšek 2012).

However, all the referenced procedures are based on simulations which are performed at the level of a MDOF model. Recently, an approximate procedure utilizing a deterministic MDOF model and uncertainty analysis at the level of a SDOF model was proposed (Kosič et al. 2014). It can be classified as being somewhere in between the aforementioned procedures for the determination of fragility parameters on the basis of pushover methods, both in terms of computational time and in terms of accuracy. Such an approach is computationally less demanding, since all the simulations are performed at the level of the so-called probabilistic SDOF model. It can therefore be attractive for the fragility analysis of more extensive building stock.

Example: Pushover-Based Seismic Fragility Analysis of the RC Frame Building With Consideration of Ground-Motion Randomness and Modeling Uncertainty

A simple variant of a pushover-based fragility analysis is demonstrated by means of an illustrative example. The procedure involves conventional pushover analyses and the nonlinear dynamic analyses of corresponding SDOF models. The effects of ground-motion and modeling uncertainties are accounted for, respectively, by the set of ground motions and the set of structural models which are generated by Monte Carlo with LHS. The step-by-step procedure for the determination of the fragility curve is as follows:

1. *Preparation of data regarding the structure and the seismic hazard at the location of the structure.* It is important to obtain as accurate as possible data regarding the seismic hazard in order to reduce the effect of uncertainties.

- Information regarding the seismic hazard and the soil type are important for the selection of appropriate ground motions.
2. *Definition of limit states.* In general, limit states can be defined at the component or structural level. As briefly discussed above, there is no critical restriction regarding the definition of limit states if the seismic demand is based on a pushover analysis procedure.
 3. *Identification of epistemic uncertainties.* Uncertainties are often divided into aleatoric and epistemic, although there is no need to make such a distinction. In this example, the aleatoric uncertainties are accounted for by the set of ground motions (step 5), whereas the effects of the epistemic uncertainties are incorporated by the set of structural models. The most important sources of epistemic uncertainty should be modeled by appropriate random variables.
 4. *Determination of the set of structural models utilizing Monte Carlo with LHS.* The LHS technique uses stratification of the probability distribution function of the random variables and consequently requires fewer simulations in comparison with a crude Monte Carlo simulation. However, any appropriate LHS technique can be used in order to generate the sample of the uncertain input parameters. It has been previously shown (e.g., Dolšek 2012) that the effect of epistemic uncertainties can be simulated with sufficient accuracy by a number of structural models, which is at least twice the number of random variables. It is worth emphasizing that the nonlinear structural model should implicitly account for cyclic deterioration.
 5. *Selection of an appropriate set of ground motions.* Many different procedures exist for the selection of an appropriate set of ground motions. Ground motions are usually selected to match the target spectrum, which is, in the simplest case, the elastic acceleration spectrum prescribed by a building code.
 6. *Calculation of pushover curves for all the structural models simulated in step 4.* Different types of pushover analysis can be performed. Conventional pushover analysis, which is based on the invariant lateral load, is the simplest and is the most often applied. The results of the pushover analysis are pushover curves and the seismic demand on the structure given the top displacement. In general, more than one pushover analysis per structural model is required.
 7. *Determination of the SDOF models.* This step requires the transformation of top displacement and base shear to the displacement (Eq. 9) and force (Eq. 14 or Eq. 18) of the SDOF model. The force-displacement relationship of the SDOF model should be multi-linear. Negative post-capping stiffness can also be applied in order to estimate the collapse capacity. It is usually assumed that the hysteretic behavior is the same as that prescribed for the components of the structural models. The mass of the SDOF model should be determined according to Eq. 7a, whereas the damping can be proportional to mass and/or stiffness (Eq. 24).
 8. *Response history analyses for all SDOF models and ground motions.* Since, in the case of SDOF models, the response history analysis is not computationally demanding, it is recommended that the records should be scaled and that the relationship between the ground-motion intensity and the displacement of the SDOF model should be computed for several levels of damage, e.g., from elastic behavior to collapse.
 9. *Assessment of seismic demand at the level of structural model.* The displacement obtained from the response history analysis of the SDOF model should be transformed to the top displacement using Eqs. 8 and 9. Any other engineering demand parameter at the level of structure can be obtained from the results of the pushover analysis on the basis of the known top displacement. However, if more than one pushover analysis is performed per structural model, in order to account for the effect of higher failure modes, then the total demand can be obtained by enveloping the results of all pushover

Analytic Fragility and Limit States [P(EDP|IM)]: Nonlinear Static Procedures, Fig. 1 A view of the investigated four-story building and the reinforcement in selected columns and beams

analyses (e.g., Brozovič and Dolšek 2014) or by combining the results together according to an appropriate combinational rule (Chopra and Goel 2002). The results of this step are samples of the engineering demand parameters given the intensities or samples of limit-state intensities.

10. *Calculation of the fragility parameters and the fragility curve.* Fragility curves can be directly estimated on the basis of the sample values. In the case when the fragility curves are based on an assumed lognormal distribution, the method of moments, the maximum likelihood method, the method of counted percentiles, or any other suitable method can be used to calculate the median engineering demand parameters or the limit-state intensities and the corresponding dispersions.

The application of the above-described step-by-step procedure for the determination of the fragility curves is demonstrated by means of a four-story reinforced concrete frame building (Fig. 1), which was previously analyzed (Dolšek 2012). Just a brief overview of the procedure is presented.

Step 1. The structure was designed for a peak ground acceleration of 0.3 g, soil type B, and

ductility class high (behavior factor = 5). Concrete of quality C25/30 and B500 Tempcore reinforcing steel were used to construct the building. Minimum and maximum mean concrete strengths of 32 MPa and 56 MPa were measured. The modulus of elasticity of the concrete varied from 28.5 to 35.3 GPa. The mean yield strength exceeded the characteristic yield strength by between 10 % and 20 %, depending on the diameter of the reinforcing bars. However, the average value of the yield strength of the reinforcing steel amounted to about 580 MPa.

Step 2. Fragility analysis was performed for the limit states of damage limitation (DL), significant damage (SD), and near collapse (NC), as defined in Eurocode (CEN 2005). It was assumed that the DL limit state is attained at the structural level if the longitudinal reinforcement in all the columns in any story starts to yield. It was further assumed that the SD and NC limit states are reached, at the structural level, when the moment exceeds the maximum moment in the case of the first column or the rotation exceeds the ultimate rotation in the case of first column, respectively. However, additional criteria for the occurrence of the SD and NC limit states were

defined. It was assumed that the top displacement corresponding to the NC limit state should not be less than that associated with 80 % of the maximum base shear measured in the post-capping range of the pushover curve. Similarly, it was assumed that the top displacement corresponding to the SD limit state should be not less than the 75 % of the NC limit-state top displacement.

Step 3. Since full knowledge about the building structure was available, only the following modeling uncertainties were considered in the fragility analysis: mass, strength of the concrete and the reinforcing steel, effective slab width, damping, and the model for determining the initial stiffness and ultimate rotation in the plastic hinges of the beams and columns. A normal or lognormal distribution was assumed for the majority of the nine random variables ($N_{\text{var}} = 9$). The statistical characteristics of the input random variables were taken from literature as reported elsewhere (Dolšek 2012). All the considered input random variables were assumed to be uncorrelated with respect to the story masses, which were assumed to be perfectly correlated and modeled by one random variable. The highest value of the coefficient of variation was adopted for the prediction of the ultimate rotations in the beams (0.6) and columns (0.4).

Step 4. Realization of the random variables was based on the LHS technique. The size of the sample was assumed to be equal to 20, which is slightly larger than twice the number of all the random variables considered in the fragility analysis. The correlation matrix of the sample was almost identical to the target correlation matrix. Note that this is only a necessary condition for the prediction of the seismic response parameters with the required accuracy, whereas the sufficient condition is related to the number of simulations, which is, in the case of the example, relatively low ($N_{\text{sim}} = 20$). However, the results of performed studies have shown that, in the case when N_{sim} is larger than twice the number of random variables (N_{var}), an increase in the number of simulations does not significantly

affect the estimated median seismic response parameters and the corresponding dispersion. The results of this step were 20 structural models based on the sample of random variables. For comparison, an additional “deterministic” structural model was also created by assuming median values of the random variables.

Step 5. A set of 14 ground motions ($N_{gm} = 14$) were selected from European Strong Motion Database to match the Eurocode-based acceleration spectrum. All the selected records were recorded on stiff soil and had peak ground acceleration greater than $0.1g$. The mean acceleration spectrum of the selected ground motions matched reasonably well with the target Eurocode-based spectrum. It should be noted that ground motions selected in this way often overestimate the seismic response with respect to that based on hazard-consistent ground motions.

Step 6. The lateral load pattern for conventional pushover analyses was based on the first vibration mode (Eq. 15). For simplicity, the structure was analyzed in the Y direction only (see Fig. 1). The pushover curves for all structural models from *Step 4* are presented in Fig. 2. An extensive scatter can be observed in the case of the deformation capacity of the realized structural models, whereas the difference in the strength is less. However, no significant differences can be observed between the deterministic model and the so-called median pushover curve. The limit-state top displacement and the corresponding base share are highlighted for the DL, SD, and NC limit states. The high coefficient of variation of the limit-state top displacement, which increases gradually with respect to the severity of the limit state, is partly the consequence of the high coefficient of variation of the input parameters and partly the consequence of the formation of different system failure modes, which were observed from pushover analyses.

Step 7. The pushover curves were idealized by means of a trilinear force-displacement relationship, also taking into account negative post-capping stiffness. Transformation of the

Analytic Fragility and Limit States [P(EDP|IM)]: Nonlinear Static Procedures, Fig. 2

The pushover curves corresponding to the structural models based on the LHS technique, the pushover curve corresponding to the deterministic model, and the median pushover curve. The points on the pushover curve represent the limit-state top displacements

idealized pushover curve to the parameters of an equivalent SDOF model was performed by dividing the base shear and top displacement of the idealized pushover curve by a transformation factor F (Eq. 8). The mass of the SDOF model and the force-displacement relationships of the SDOF model were obtained according to Eq. 7a and Eqs. 9 and 18, respectively. Note that the number of the SDOF models was the same as the number of pushover curves. All the parameters of the SDOF models differed from one another due to the epistemic uncertainties. However, the peak-oriented hysteretic model and damping proportional to the tangent stiffness were assumed to be invariant.

Step 8. The response history analyses were performed for each SDOF model by scaling the ground-motion intensity in order to obtain the complete relationship between the peak ground acceleration and the displacement of the SDOF model. The results are presented in Fig. 3, where the highlighted points indicate the limit-state intensities which were used for the calculation of the fragility parameters.

Steps 9 and 10. The limit-state top displacements highlighted in Fig. 2 were transformed into the displacement of the corresponding SDOF model, which was then used to determine the limit-state intensities. The limit-state displacements and the limit-state intensities

shown in Fig. 3a are presented for the deterministic SDOF model, taking into account just ground-motion randomness. The variability can be observed only for the limit-state intensities, while in the adjacent figure (Fig. 3b), variability can be observed also for the limit-state displacements. The latter variability is the consequence of the effect of epistemic uncertainty. The sample of limit-state intensities presented in Fig. 3b was used to estimate the parameters of the fragility curves. The median values and the corresponding dispersion of natural logarithms were estimated according to maximum likelihood method. The fragility curves were then obtained using Eq. 26. The results are presented in Fig. 4.

A flatter fragility curve can be observed in the case of the DL limit state if the effects of epistemic uncertainty are considered in the fragility analysis. This is in agreement with expectations and can be modeled by using the mean estimate approach, in which it is assumed that the effects of epistemic uncertainties on the fragility curve can be modeled by simply inflating the dispersion. However, in the case of the NC limit state, it is clear that incorporating the epistemic uncertainties in the determination of the fragility curve causes a shift of the fragility curve to the left, which means that the effects of epistemic

uncertainty reduced the median limit-state intensity. This effect was frequently observed, especially in the case of reinforced concrete frames.

Summary

Pushover-based methods are used around the world as a tool for the approximate seismic performance assessment of structures. Due to their

computational efficiency, pushover-based methods are attractive also for fragility analysis, which incorporates the effects of ground motions and other sources of uncertainty. In this entry, emphasis was placed on explaining the theoretical background for predicting seismic demand using a SDOF model, since it is important to understand the basic assumptions of the approximate methods. A variant of the pushover-based fragility analysis is then explained through a

step-by-step procedure and demonstrated by means of an example of a four-story building. It has been shown that pushover-based methods can be successfully used for fragility analysis. However, the analyst should always be aware of the approximate nature of pushover-based methods. Such an awareness will allow him to decide to which type of structures and for what purpose individual pushover-based methods can be applied.

Classical monuments

Introduction

Classical monuments are made of structural elements (called drums in case of columns), which lie one on top of the other without mortar. Columns are connected to each other with architraves (epistyles) consisting of stone beams, usually made of marble. A characteristic example is shown in Fig. 1 from the Olympieion of Athens, Greece.

Architrave beams are usually connected to each other with iron clamps and dowels. However, in most cases no structural connections are provided between the drums of the columns. Only in few cases, iron shear connectors (dowels) are provided at the joints, which restrict, up to their yielding, sliding but do not affect rocking. The wooden dowels that were usually placed at the joints among the drum of the columns were aiming at centering the stones during construction and, practically, do not have any effect on their seismic response.

Due to their spinal construction, columns of ancient monuments respond to strong earthquakes with intense rocking and sliding of the drums. Therefore, the dynamic analysis of ancient monuments is a difficult problem to treat, since it does not follow the behavior rules of continuum systems.

Several investigators have examined the seismic response of classical monuments and, in general, of stacks of rigid bodies analytically, numerically, or experimentally, mostly using

two-dimensional models (e.g., Allen et al. 1986; Sinopoli 1989; Psycharis 1990; Winkler et al. 1995; Psycharis et al. 2000; Konstantinidis and Makris 2005; Papaloizou and Komodromos 2009 among others) and lesser three-dimensional ones (e.g., Papantonopoulos et al. 2002; Mouzakis et al. 2002; Psycharis et al. 2003, 2013; Dasiou et al. 2009a, b). These studies have shown that, due to the domination of rocking, the characteristics of the response are similar to the ones of the simplest case, the rocking of a rigid block. They have also shown that these structures, despite their apparent instability to horizontal loads, are, in general, earthquake resistant (Psycharis et al. 2000), which is also proven from the fact that many classical monuments built in seismic prone areas have survived for almost 2,500 years.

In general, the dynamic behavior of ancient monuments is highly nonlinear and complicated. The abovementioned extensive numerical and experimental investigations have shown that such structures do not possess natural modes in the classical sense and the period of free vibrations is amplitude dependent. During a strong earthquake the response alternates between different “modes” of vibration, each one being governed by a different set of equations of motion. As a result, the response is highly nonlinear. An example of this nonlinearity is that a column may collapse under a certain earthquake motion and be stable under the same excitation magnified by a value greater than one.

In addition, the response is very sensitive to even trivial changes of the parameters of the system or the excitation. This was verified during experiments, since “identical” experiments produced significantly different results in some cases. The sensitivity of the dynamic behavior was also evident in the numerical analyses, in which trivial changes in the excitation or the system parameters changed the response significantly. Another effect of the response sensitivity is the significant out-of-plane displacements observed for purely planar excitations: in some experiments, the deformation in the direction normal to the plane of the excitation was of the same order of magnitude with the principal deformation.

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 1 SE corner of the Olympieion of Athens, Greece

The vulnerability of classical monuments to earthquakes depends on two main parameters: (i) the predominant period of the ground motion and (ii) the size of the structure. The period of the excitation affects significantly the response and the risk of collapse, with low-frequency earthquakes being much more dangerous than high-frequency ones. In the first case, the response is characterized by intensive rocking, while in the latter rocking is usually restricted to small values, but significant sliding of the drums occurs, especially at the upper part of the structure. In this sense, near field ground motions, which contain long-period directivity pulses, might bring these structures to collapse. The size of the structure is another important parameter, with bulkier structures being much more stable than smaller ones with the same aspect ratio of dimensions.

Despite their apparent instability, classical monuments without significant damages are not

vulnerable to usual earthquake motions. However, collapse can occur much easier if imperfections are present, as cutoff of drums, displaced drums, inclined columns due to foundation failure, etc. Such imperfections are common in ancient monuments and may endanger the safety of the structure in future earthquakes.

It is evident that the dynamic analysis of classical monuments for earthquake loads is a very important part of the restoration/preservation process. However, it is not an easy task. Due to the complicated response, such analyses can only be performed using powerful computational codes that can account for rocking, sliding, and even complete separation of the individual stones. Additionally, all such analyses are inevitably based on assumptions concerning the material and joint properties, some of which are difficult to evaluate. Therefore, and taking under consideration the sensitivity of the response, one must have in mind that any dynamic analysis of an ancient monument contains a certain amount of doubt. In any case, the earthquake response of ancient monuments does not follow general rules, and each monument deserves a case-by-case investigation that focuses on the specific monument, recognizing its current condition and local seismic hazard.

In this article, the basic features of the dynamic response of multi-drum columns and colonnades are presented, and critical points regarding their modeling and analysis for seismic loads are discussed. First, the important features of the simplest case, the rocking block, are presented. Then, the dynamics of multi-drum columns and groups of columns (colonnades) are discussed, while emphasis is given to the sensitivity of the response to several parameters of the numerical model. Finally, guidelines regarding the proper selection of base motion acceleration time histories to be used in the analyses are presented.

Rocking Response of a Rigid Block

Despite its apparent simplicity, the rocking response of a rigid block sitting on a rigid base

Ancient Monuments Under Seismic Actions: Modeling and Analysis,

Fig. 2 Rocking of a rigid block on a rigid base without sliding: (a) positive angle of rotation; (b) negative angle of rotation

is a complicated problem that has attracted the interest of many researchers in the last century. The basic scope of these investigations has been the estimation of the required intensity of the ground motion to overturn slender bodies during strong earthquakes. The first attempts towards this aim were made by Milne (1885), Milne and Omori (1893) and Kirkpatrick (1927). However, it was Housner (1963) who first tackled the problem systematically, deriving the equations of motion that govern the rocking response of a rigid, freestanding block and examining the overturning risk under simple ground pulses.

Equation of Motion

Let us consider the rocking block shown in Fig. 2. The block and the base are considered rigid, and the coefficient of friction is assumed to be large enough to prevent sliding of the block. In Fig. 2, a rectangular block is shown, with dimensions: width of the base = b and height of the center of mass (CM) from the base = h . However, the equations of motion and the basic features of the response that are presented in the following are also valid for any symmetric block in the vertical direction with such dimensions and arbitrary shape.

Assuming that the block has been set into rocking motion, the rotation can either happen

about corner O of the base (Fig. 2a), which corresponds to positive angles of rotation (clockwise), or about corner O' of the base (Fig. 2b), which corresponds to negative angles of rotation (counterclockwise). The distinction between positive and negative angles of rotation is essential, because a different equation governs the motion in each case.

Under a horizontal base excitation $\ddot{x}_g(t)$, the equation of motion can easily be derived by applying Newton's second law for the moments about the pole of rotation (point O for positive rotations, point O' for negative rotations) and taking under consideration that, apart from the weight, a horizontal inertial force (d' Alembert force) acts at CM, equal to $-m\ddot{x}_g(t)$. Then, the equation of motion can be written in the form:

$$I_O \ddot{\varphi} \pm mgr \sin(\theta \mp \varphi) = -m\ddot{x}_g r \cos(\theta \mp \varphi) \quad (1)$$

where φ is the rocking angle, m is the mass of the block, r is the distance of CM from the pole of rotation (point O or O'), θ is the slenderness angle defined by $\theta = \tan^{-1}b/(2h)$, I_O is the mass moment of inertia about O or O', and g is the acceleration of gravity. In this equation, whenever a double sign appears, the upper one

corresponds to $\varphi > 0$ (clockwise rotation) and the lower one to $\varphi < 0$ (counterclockwise rotation).

Introducing the parameter p defined by

$$p^2 = \frac{mgr}{I_O} \quad (2)$$

and using the $\text{sgn}()$ function, Eq. 1 can be written in the following general form:

$$I_O \ddot{\varphi} + p^2 \sin[\theta \text{sgn}(\varphi) - \varphi] = -p^2 \cos[\theta \text{sgn}(\varphi) - \varphi] \quad (3)$$

The parameter p is a characteristic frequency of the system. Actually it is equal to the pendulum frequency of the block when hung about the corner of the base.

As mentioned above, Eqs. 1 and 3 are valid for any rigid block with an axis of symmetry about the vertical axis through CM, with I_O being the mass moment of inertia about the corner of the base. In the special case of a homogeneous rectangular block, I_O is given by the following relation:

$$I_O = \frac{m[b^2 + (2h)^2]}{3} = \frac{4mr^2}{3}, \quad (4)$$

and the characteristic frequency p becomes

$$p = \sqrt{\frac{3g}{4r}} \quad (5)$$

For small angles of rotation ($\varphi \ll 1$), Eq. 1 can be linearized about the equilibrium position assuming that $\cos \varphi \approx 1$ and $\sin \varphi \approx \varphi$ and neglecting the second order term containing the product $\varphi \cdot \ddot{x}_g(t)$. Taking under consideration that $r \sin \theta = b/2$ and $r \cos \theta = h$, the following linearized equation can be derived:

$$I_O \ddot{\varphi} - mgh\varphi = \mp mg \frac{b}{2} - mh\ddot{x}_g \quad (6)$$

For large angles of rotation, when the block is close to the verge of overturning, the linearization should be performed about the point of unstable

equilibrium assuming that $|\theta \mp \varphi| \ll 1$, thus $\cos(\theta \mp \varphi) \approx 1$ and $\sin(\theta \mp \varphi) \approx (\theta \mp \varphi)$. Then, Eq. 1 becomes

$$I_O \ddot{\varphi} - mgr\varphi = \mp mgr\theta - mr\ddot{x}_g \quad (7)$$

It is noted that, as evident from Eqs. 6 and 7, the rocking block corresponds to a system with negative stiffness. Also, for slender blocks with slenderness angle θ less than about 20° , the linearized Eqs. 6 and 7 do not differ significantly, since $\tan \theta \approx \sin \theta \approx \theta$. Analyses of such blocks showed that the linearized equations can predict with acceptable accuracy for engineering purposes the response and the overturning risk of the block.

Impact with the Ground

During rocking, the pole of rotation alternates from point O to O', or vice versa. The alteration of the pole of rotation takes place when the block hits the ground and is accompanied by energy dissipation due to the change in the velocity of the center of mass which is schematically shown in Fig. 3. Let us assume that the angular velocity before impact is $\dot{\varphi}_1$ and after impact is $\dot{\varphi}_2$. Then, one can write

$$\dot{\varphi}_2 = \varepsilon \cdot \dot{\varphi}_1 \quad (8)$$

where ε is a coefficient of restitution. If we assume that the impact is fully plastic, i.e., that there is no rebound of the block on the base, the value of ε can be calculated applying the principle of conservation of the angular momentum about point O' before and after impact (Housner 1963), which gives

$$\varepsilon = 1 - \frac{mb^2}{2I_O} \quad (9)$$

Equation 9 implies that the coefficient of restitution ε and the dissipated energy depend solely on the geometry of the block. However, experimental investigation (e.g., Priestley et al. 1978; Aslam et al. 1980) showed that the actual value of ε might be significantly different than the theoretical value of Housner, depending on the

Ancient Monuments Under Seismic Actions: Modeling and Analysis,

Fig. 3 Change in the velocity of the CM during impact from positive to negative angles of rotation: (a) immediately before impact, when the pole of rotation is point O; (b) immediately after impact, when the pole of rotation is point O'

materials of the block and the base. For this reason, in many analyses ε is considered an independent parameter of the problem rather than been calculated from Eq. 9.

Free Vibrations

In case that the block is rocking freely ($\ddot{x}_g(t) = 0$), the linearized equation of motion (7) becomes

$$\ddot{\varphi} - p^2 \varphi = \mp p^2 \theta \quad (10)$$

where p is given by Eq. 2. Note that p is not the eigenfrequency of the system, since, due to the negative stiffness, rocking blocks do not possess eigenfrequencies in the classical sense. The solution of Eq. 10 is

$$\varphi(t) = A \cosh(pt) + B \sinh(pt) \pm \theta \quad (11)$$

where the coefficients A and B are determined from the initial conditions. For example, for an initial tilt of the block, $\varphi_0 < \theta$, the initial conditions are $\varphi(t=0) = \varphi_0$ and $\dot{\varphi}(t=0) = 0$, and Eq. 11 becomes

$$\varphi(t) = \theta - (\theta - \varphi_0) \cosh(pt) \quad (12)$$

Equation 12 describes the motion of the block around point O as it comes back to the

equilibrium position with positive angles of rotation. When φ becomes zero, the block hits the base and the rotation continues around point O' with the motion been described by the equation describing negative rotations. According to Eq. 8, the initial angular velocity of this motion is reduced compared with the velocity of the block when it hits the base. Due to the different equations of motion describing each regime of the response, the overall behavior is nonlinear.

If there was not any dissipation of energy during impact, the time elapsed from the angle of maximum tilt (initially equal to φ_0) up to the point when the block reaches the equilibrium position ($\varphi = 0$) would correspond to one fourth of the period T of free vibrations. Therefore, setting $\varphi = 0$ for $t = T/4$ in Eq. 12, the period of free vibrations can be calculated:

$$T = \frac{4}{p} \cosh^{-1} \left(\frac{1}{1 - \varphi_0/\theta} \right) \quad (13)$$

However, in real structures dissipation of energy does occur at each impact. For this reason, the block will attain a reduced maximum tilt after each impact, and the period of free vibrations will continuously decrease. Using Eq. 8,

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 4 Dependence of the period of free vibrations on the normalized initial tilt, φ_0/θ

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 5 Variation of the amplitude of free vibrations with the number of impacts for $\varepsilon = 0.7$

Housner (1963) calculated that the amplitude φ_n of the free vibrations after the n^{th} impact is

$$\frac{\varphi_n}{\theta} = 1 - \sqrt{1 - \varepsilon^n \left[1 - \left(1 - \frac{\varphi_0}{\theta} \right)^2 \right]} \quad (14)$$

The plot of the dimensionless product pT versus the normalized initial tilt angle, φ_0/θ (Eq. 13), is given in Fig. 4, while in Fig. 5 the decrease of the amplitude with the number of impacts is plotted for $\varepsilon = 0.7$ and various values of the normalized initial tilt, φ_0/θ .

Initiation of Rocking Under Earthquake Excitation

Under a seismic ground excitation $\ddot{x}_g$, rocking starts when the base acceleration reaches

a critical value, $(\ddot{x}_g)_{cr}$. At that time, the overturning moment about O or O' due to the d'Alembert inertial force, $M_A = m (\ddot{x}_g)_{cr} h$, becomes equal with the restoring moment due to the weight of the block, $M_E = mgh/2$; therefore

$$(\ddot{x}_g)_{cr} = (\tan \theta)g \quad (15)$$

For slender blocks ($\theta < 20^\circ$), the critical base acceleration can be approximated by

$$(\ddot{x}_g)_{cr} = \theta g \quad (16)$$

If the peak acceleration of the base motion, pga , is smaller than $(\ddot{x}_g)_{cr}$, the earthquake is not strong enough to initiate rocking of the block.

Ancient Monuments Under Seismic Actions: Modeling and Analysis,

Fig. 6 (a) El Centro (1940) earthquake. (b) Rocking response of an orthogonal block of dimensions $b = 0.50$ m, $2h = 1.5$ m for the El Centro earthquake amplified to several values of pga (for $\varepsilon = 0.85$)

As evident from Eq. 15, the slenderer the block, the smaller is the required base acceleration to set it into rocking motion.

Nonlinearity and Sensitivity of the Response

As mentioned above, the rocking response is highly nonlinear. This is illustrated in Fig. 6b, in which the time history of the angle of rotation of an orthogonal block with dimensions $b = 0.50$ m, $2h = 1.50$ m is shown for the El Centro (1940) earthquake (Fig. 6a) amplified to four different values of the peak ground acceleration: $pga = 0.60$ g, 0.70 g, 0.80 g, and 0.90 g. In all cases, the coefficient of restitution was set to $\varepsilon = 0.85$, which corresponds to Housner's theoretical value according to Eq. 9. It is seen that the response of the block is stable for $pga = 0.60$ g (blue line), while the block overturns in the direction of positive rotations for $pga = 0.70$ g (green line). Increasing the base excitation to $pga =$

0.80 g the block overturns in the opposite direction (negative rotations). However, if the base motion is amplified even more to $pga = 0.90$ g, the response is stable again and overturning does not occur (gray line).

Apart from the nonlinearity, another characteristic of the response is its sensitivity to even trivial changes of the parameters. This sensitivity has been proven by the non-repeatability of the same experiment (Yim and Chopra 1984). In Fig. 7, the sensitivity of the response of the abovementioned block to the value of the coefficient of restitution ε is shown. In this plot, the response of the block is shown for the El Centro record amplified to $pga = 0.50$ g and for three values of the coefficient of restitution: $\varepsilon = 0.85$ (Housner's value), $\varepsilon = 0.87$, and $\varepsilon = 0.88$.

It is seen that the response for $\varepsilon = 0.87$ (green line) is very similar with the one for $\varepsilon = 0.85$

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 7 Rocking response of an orthogonal block of dimensions $b = 0.50$ m, $2h = 1.5$ m for the El Centro earthquake amplified to $pga = 0.50$ g for various values of the coefficient of restitution ε

(blue line), except for an additional small rocking response of the block around $t = 5$ s, which does not occur for $\varepsilon = 0.85$. However, if we slightly increase the coefficient of restitution to $\varepsilon = 0.88$, intense rocking occurs after $t = 4$ s with significantly larger amplitude than the amplitude in the time interval $2.0 < t < 3.5$ s when all the rocking response takes place for $\varepsilon = 0.85$. It is interesting to notice that this intense rocking for $\varepsilon = 0.88$ occurs after the strong motion of the ground excitation (see Fig. 6a).

It must also be noted that although, in general, a decrease in the value of ε leads to smaller rocking amplitude, due to the larger dissipation of energy during impact, it is also possible that a smaller coefficient of restitution produces larger rocking response (Aslam et al. 1980). This counterintuitive phenomenon is attributed to the nonlinearity of the response.

Main Features of the Rocking Response

Except for the abovementioned nonlinearity and the sensitivity of the response, an important feature of the dynamic behavior is its dependence on the dimensionless quantity pT_p with T_p being the predominant period of the ground motion. Actually, for harmonic excitation (which can be extrapolated to pulse-like ground motions) the normalized response can be expressed solely as a function of four dimensionless terms (Zhang and Makris 2001; Dimitrakopoulos and DeJong 2012):

$$\frac{g \cdot \varphi_{\max}}{pga} = f\left(pT_p, \frac{g \tan \theta}{pga}, \tan \theta, \varepsilon\right) \quad (17)$$

Assuming that ε is known, Eq. 17 implies that:

- For a given base excitation (given pga and T_p), the response depends on the slenderness θ and the characteristic frequency p . The latter is a function of the size of the block. The value of p decreases inversely with the size of the block (e.g., see Eq. 5 for an orthogonal block), measured with the distance r . Therefore, for the same slenderness there is an important size effect on the response. Actually, among two blocks with the same slenderness θ but different size, the smaller one will experience more intense rocking than the larger one. This is shown in Fig. 8, in which the response of two blocks with $\tan \theta = 0.5$ but different size ($b = 0.50$ m for the left block and $b = 1.5$ m for the right) is shown for the same impulse base excitation. It is seen that the small block overturns, while the large one does not.
- For a given block (given θ and p), the rocking response and the overturning risk greatly depend on the predominant period of the base excitation. In general (for details see Zhang and Makris 2001; Dimitrakopoulos and DeJong 2012), the required normalized amplitude of the base acceleration, $pga/(g \tan \theta)$, to cause overturning decreases as the

Ancient Monuments Under Seismic Actions: Modeling and Analysis,

Fig. 8 Rocking response of two similar orthogonal blocks of the same slenderness ($\tan \theta = 0.5$) and different size (base width $b = 0.50$ m in the *left* block and $b = 1.50$ m in the *right*) for the same impulse base excitation

period T_p increases. In other words, the block is more vulnerable to long-period earthquakes than to high-frequency ones.

It should be noted that the inequality $\varphi > \theta$ is a necessary but not a sufficient condition for overturning to occur, since it is possible that the rocking angle attains temporarily values larger than θ (i.e., $\varphi_{\max} > \theta$) without overturning. Of course such cases are exceptional, since for $\varphi > \theta$ the weight of the block produces an overturning moment instead of a restoring one; thus, the block will not topple only if at the same time a quite large restoring inertial force develops due to the ground motion, capable to reverse this situation and bring the block back to stable state.

Dynamics of Multi-drum Columns and Colonnades

Difficulties and Uncertainties of the Dynamic Analysis

As mentioned in the Introduction, columns of ancient monuments are made of individual structural elements, called drums, which are put one on top of the other without mortar or any other connecting material (Fig. 9). The wooden dowels that were usually placed at the joints between the

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 9 Photo of a single standing and a fallen column of the Olympieion of Athens, Greece, showing the multi-drum construction of ancient columns

drums of the columns were aiming at centering the stones during construction and, practically, do not have any effect on the seismic response. In few cases steel connections (dowels) are

Ancient Monuments Under Seismic Actions: Modeling and Analysis,

Fig. 10 The four rocking “modes” of vibration of a two-block assembly (Psycharis 1990)

provided at the joints, which restrict, up to their yielding, sliding but do not affect, in general, rocking.

Due to their spiral construction, ancient columns respond to strong earthquakes with intense rocking and sliding of the drums. In addition, due to the cylindrical shape of the drums, wobbling also occurs during rocking. Usually, rocking dominates the response of multi-drum columns, which, for this reason, is characterized by the strong nonlinearity and the sensitivity discussed in the previous section. In addition, the analysis is extremely difficult and complicated due to the many “modes” of response in which multi-block systems can respond, as it will be discussed in the ensuing.

Furthermore, there is a number of other uncertainties associated with the seismic analysis of ancient monuments: the existing damage, which might be crucial to the stability of the monument to future earthquakes but is difficult to implement in the numerical models; the difficulties in representing accurately the real geometry; and the “vague” properties that must be assigned to the joints in the numerical models. All these issues will be discussed in the following; however, taking into consideration the sensitivity of the rocking response to even small changes in the parameters, one must have in mind that, no matter how accurate an analysis is, there is always an inherent uncertainty in the results.

Analysis of the Dynamic Response

The dynamic response of multi-drum columns, and, in general, of stacks of rigid blocks, is

governed by the motion of the stones, which can rock and slide individually or in groups. In case of cylindrical drums, wobbling also occurs during rocking. The dynamic analysis of such systems is a difficult task that can only be treated numerically, since there are many different “modes” in which the structure can vibrate. For example, for a system of two blocks, there are four “modes” of rocking vibrations, shown in Fig. 10 (Psycharis 1990). In case of multi-drum columns, the corresponding modes increase exponentially with the number of the drums and, for typical columns with many drums, can be tens of thousands.

It is noted that the term “modes” of vibration is used here to denote the different patterns of the response. These “modes” of response must not be confused with the “eigenmodes” of continuous systems. Rocking structures do not possess natural modes in the classical sense.

Under an earthquake excitation, the response of the column continuously alternates from one “mode” to another (Fig. 11). Each “mode” is governed by a different set of equations of motion, while criteria must be defined for the transition between “modes.” It is evident, therefore, that sophisticated numerical codes are needed for the dynamic analysis of ancient monuments, able to take under consideration the sliding of the drums, the opening of the joints (rocking), and even complete separation and recontact of the drums.

In general, numerical models for the analysis of masonry structures may be classified into two major conceptual classes: (i) equivalent

Ancient Monuments Under Seismic Actions: Modeling and Analysis,

Fig. 11 Response of two columns of Olympieion of Athens at two different time instances during intense ground shaking. The geometry of the two columns is slightly different (the *left* has 14 drums and the *right* 15) leading to different “modes” of vibration (numerical results obtained with 3DEC software)

A

continuum models, in which the influence of the joints between blocks is introduced by means of special constitutive relations, and (ii) discontinuous models, in which the joints are represented explicitly, leading to an idealization of the structure model as a block assemblage. The finite element method is the preferred numerical tool for models of the first type, while either finite element implementations with joint elements or discrete element methods are capable of handling the second type.

For stone masonry structures, particularly those composed of multi-drum columns and architraves as ancient monuments, block models are an obvious option. Deformation and failure of these structures is mainly governed by the relative movements between blocks. The blocks can be assumed rigid without significant loss of precision.

One method that has been proven to be very efficient in dealing with such systems is the distinct (or discrete) element method (DEM) introduced by Cundall in the 1970s in the context of rock mechanics and later extended to three-dimensional problems (Cundall 1988). The code 3DEC (Itasca 1998), which was used for most of the analyses presented herein, is based on DEM.

This method provides the means to apply the conceptual model of a masonry structure as a system of blocks. The system deformation is concentrated at the joints, where frictional sliding or complete separation may take place.

The method calculates the displacements and the forces in the individual blocks and applies compatibility laws to detect new contacts between the bodies. DEM employs an explicit algorithm for the solution of the equations of motion of the blocks, taking into account large displacements and rotations (Itasca 1998; Papantonopoulos et al. 2002).

Comparison of experimental (shaking table) data concerning the seismic response of a marble drummed replica of a column of the Parthenon in 1:3 scale with the numerical results produced by 3DEC (Papantonopoulos et al. 2002) showed satisfactory agreement in the maximum displacements during the seismic motion and in the residual deformation of the column (Fig. 12). Exact agreement could not be obtained, due to the sensitivity of the dynamic response to even trivial changes in the parameters (Mouzakis et al. 2002; Dasiou et al. 2009a). For example, repetition of the same experiment led to different results in many cases. An example is shown in Fig. 13, in which the recorded response during two similar experiments (EQ14 and EQ15) is depicted, showing significantly different residual deformation. The differences between these “similar” experiments were (i) trivial differences in the initial geometry of the column due to slightly different (not visible) relocation of the drums at their initial position and (ii) small difference (less than 2 %) in the shaking table motion. It is interesting to note that the numerical analyses also

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 12 Comparison of experimental (shaking table) and numerical (3DEC) results concerning the horizontal displacement at the top of the capital of

a 1:3 replica of a column of the Parthenon under seismic excitation: (a) x-direction; (b) y-direction (Papantonopoulos et al. 2002)

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 13 Horizontal displacement at the top of the capital of a 1:3 replica of a column of the

Parthenon under seismic excitation for the same experiment repeated twice (Papantonopoulos et al. 2002)

showed different response, caused by the abovementioned small difference in the base excitation (the geometry was exactly the same in the numerical models). These comparisons, and additional ones concerning more complicated structural systems comprising of three columns connected with architraves (Dasiou et al. 2009b), showed that DEM, and specifically 3DEC, can reliably predict the seismic response of classical monuments.

It must be emphasized that the application of sophisticated numerical models for the prediction of the seismic response of ancient columns and colonnades requires the knowledge of the value of several parameters which, in general, are not known a priori (this issue is discussed in detail in

the following). In this sense, experimental data of the seismic response of multi-drum columns are extremely valuable since they can be used for the calibration of the numerical models.

Modeling Aspects

Regardless of the numerical method that will be used for the analysis of the seismic response, assigning values to the parameters of the numerical model is not a straightforward procedure. Due to the sensitivity of the response, the parameters of the numerical model and the more or less accurate geometrical representation of the structure can affect the results significantly. For this reason, experimental data are generally needed in order to calibrate these parameters, especially the

ones concerning the properties at the joints. In the following, several critical aspects related to the sensitivity of the response to several parameters are discussed.

Joint Parameters

In the distinct element method, the interaction forces between two blocks are applied at a set of contact points located at the vertex-to-face and the edge-to-edge intersections. These forces depend on the relative displacement between the blocks according to the constitutive model adopted for the joints. In the normal direction, the joint behavior is governed by the normal stiffness coefficient, k_n , which relates the contact stress with the normal contact displacement. No tensile strength is considered, so this spring element is only active in compression. In the shear direction, an elastoplastic stress-displacement law is usually assumed. The elastic range is characterized by the shear stiffness, k_s , while the shear strength is governed by the Coulomb friction coefficient, μ , with no cohesive strength component.

The appropriate values to be assigned to the stiffness coefficients k_n and k_s depend on the material of the drums. Since typical values for various materials are not provided in the literature, the assignment of these values is not easy. If experimental data are available, the coefficients can be calibrated against these data. However, such data are very few and concern specific materials only (usually marble). It is noted that loose contacts at the joints due to deteriorations of the contact surfaces might also affect the results.

One way to overcome this difficulty is to calibrate k_n and k_s so that the natural period of the column for small amplitude oscillations matches the one determined by ambient vibration measurements. It is noted that for low-amplitude vibrations multi-drum columns behave like continuous systems and do possess natural modes. This approach has the advantage that the effect of existing imperfections at the joints can be included in the joint stiffness.

Concerning the coefficient of friction, it varies from a static value μ_s at the initiation of sliding to a lower value, which degrades to the kinetic value

μ_k , where $\mu_k \leq \mu_s$. This change in friction depends not only on the normal stresses on the drum interface during sliding but also on the number of reversals and the amount of cumulative slip. A considerable number of laboratory test results on surfaces of limestone and marble specimens of different roughness can be found in literature. Although the test procedures differ, the evidence is that, with increasing normal stress σ_n , the static friction coefficient increases, while the difference $(\mu_s - \mu_k)$ decreases. This means that, other things being equal, it is easier for drums to slide in the upper parts of a multi-drum column than near its pedestal and also that, once sliding begins, the drop of the static coefficient μ_s to the residual value of μ_k may lead to larger and more rapid displacement in the upper parts than at lower levels of the shaft.

The proper assessment of the joint parameters is essential for the analysis, since they affect the response significantly. An example of the effect of the value of k_n and k_s on the response of a six-drum column with a two-piece capital is illustrated in Fig. 14 for three different combinations of the normal and shear coefficients (Toumbakari and Psycharis 2010). It is evident that the values of k_n and k_s affect both the amplitude of the response and the residual deformation of the column.

Significant might also be the effect of the coefficient of friction. An example is shown in Fig. 15 for the column of Olympieion of Athens (the existing dowels at the joints were not considered in this analysis) under a strong earthquake motion. Three values of the coefficient of friction were examined: $\mu = 0.55$, 0.75 , and 1.05 . It is noted that the typical value of μ for marble is about 0.70 – 0.75 ; thus, the value $\mu = 0.55$ is considered rather low, while the value $\mu = 1.05$ is unrealistically high. It is seen that the value of the coefficient of friction affected mainly the response and the residual dislocation of the drums at the upper part of the column, where the developed accelerations were large enough to initiate sliding.

Damping

The dissipation of energy due to sliding is automatically taken under consideration with the

Case	k_n [Pa/m]	k_s [Pa/m]
4	5×10^9	1×10^9
5	0.5×10^9	0.1×10^9
6	1×10^9	0.2×10^9

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 14 Time histories of the displacement at the top of the capital of a freestanding

column for three different sets of the joint stiffness (Toumbakari and Psycharis 2010)

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 15 Time histories of the displacement at various positions along the height of a freestanding column for three different values of the coefficient of friction

elastoplastic model of the shear stiffness. However, since elastic properties are assumed at the joints, extra damping must be introduced to the numerical model to account for the

dissipation of energy due to the impacts between drums during rocking.

Shaking table experiments on multi-drum columns showed very low attenuation. These results

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 16 Comparison of numerical results with experimental data for (a) zero damping and (b) 0.5 % stiffness-proportional damping (Papantonopoulos et al. 2002)

lead to the conclusion that, to be conservative, the numerical simulations should be performed with very low or even zero damping, at least during the strong shaking. This is illustrated in Fig. 16, in which the numerical results for zero damping and 0.5 % stiffness-proportional damping are compared with experimental data (Papantonopoulos et al. 2002). It is seen that the introduction of even a small value of damping decreased unrealistically the amplitude during the strong shaking. However, it is necessary to introduce some damping towards the tail of the response in order to attenuate the free vibrations and be able to calculate the residual deformation of the column.

In general, whenever damping is used it is preferable to use the stiffness-proportional component of Rayleigh damping. However, explicit time-stepping algorithms, such as the one in 3DEC, require rather small time steps if stiffness-proportional damping is used. Thus, in order to avoid the increase in the computational effort, only the mass proportional component of Rayleigh damping can be adopted, with a low value though.

Required Accuracy of the Geometric Representation

One question that arises in conducting numerical analyses of ancient monuments is how accurately the model must represent the actual geometry. As a general rule, the geometry should be implemented as accurately as possible, due to the sensitivity of the response. However, exact

modeling is practically impossible, due to the complicated geometry of the architectural details of the columns and the random shape of existing damage. In some cases, even the gross geometry (number and dimensions of drums) might not be easy to implement due to lack of information, since, in most monuments, the height of each drum and sometimes even the number of the drums of the columns are not constant (see Fig. 9). This happens because drums were made of marble of superior quality and the height of each drum depended on the available marble pieces, as ancient builders were trying to avoid any unnecessary loss of material.

In addition, numerical models containing large number of blocks might require extremely high computational time; thus, it might be desirable to simplify the model as much as possible.

An example of the effect of the number of drums considered in the analysis on the response of a column with a statue on top is given in Fig. 17 (Ambraseys and Psycharis 2011). In this case, the investigation concerned the risk of toppling of the statue. The column consisted of 15 drums, but analyses were also performed for columns of 5 drums, 30 drums, and 60 drums (see top of Fig. 17). In Fig. 17, the uplift of one corner of the statue is shown. It is seen that the response varied in each case while the statue overturned only in the case of the column with 15 drums.

It is evident therefore that the geometry must be implemented as accurately as possible in order to reach correct conclusions. However, if only gross results are sought, it might be adequate to

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 17 Time histories of the vertical displacement of corner 1 of the base of the statue (*blue line*) and the capital (*red line*): (a) 5-drum column, (b)

15-drum column, (c) 30-drum column, and (d) 60-drum column. Overturning of the statue occurs only in case (b) (Ambraseys and Psycharis 2011)

apply very simple geometries, which can be analyzed much easier. An example is given in Fig. 18, in which the required amplitude of a harmonic excitation to cause overturning versus the period of the excitation (stability threshold) is shown for (a) the column of the temple of Zeus at Nemea, Greece, and (b) the column of the temple of Apollo at Bassae, Greece (Psycharis et al. 2000). The results obtained for the actual geometry of the multi-block columns are compared with the ones for the equivalent single-block columns, i.e., the monolithic columns with the same overall dimensions with the

original columns. It is seen that the very simple single-block representation could predict with acceptable accuracy the overturning risk of the columns and thus it could be used as a first-order approximation within a decision making procedure.

Representation of Existing Damage

In their current condition, ruins of ancient structures present many different types of damage. Most common are missing pieces (cutoffs) that reduce the horizontal sections in contact, foundation problems resulting in tilting of the columns,

Ancient Monuments Under Seismic Actions: Modeling and Analysis,

Fig. 18 Comparison of the stability threshold for the overturning of the multi-drum column and the equivalent single-block column: (a) column of the temple of Zeus; (b) column the temple of Apollo (Psycharis et al. 2000)

dislocated drums from previous earthquakes, and cracks in the structural elements that in some cases split the block in two. Such imperfections affect significantly the stability of the columns which, thus, are much more vulnerable to earthquake excitations compared with the original intact structures. Therefore, the abovementioned impressive stability of ancient monuments against earthquakes might not be a valid assumption any more, if significant damage is present.

An example of the effect of existing imperfections on the stability of ancient columns is shown in Fig. 19 for the column of the Parthenon in Athens (Psycharis et al. 2003). The maximum permanent displacement of the column is plotted versus the *pga* of the ground motion, and it is seen that the presence of the imperfections shown in the left drawing of Fig. 19 leads to larger displacements and significantly earlier collapse.

It is evident therefore that the damage that can be observed today in the monuments must be implemented in the numerical models. It should be mentioned, however, that this is not an easy task for several reasons: (i) because the existing damage has not always been mapped in the required detail, (ii) because the shape of missing pieces is irregular and very difficult to be modeled accurately, and (iii) because certain types of damage, as cracks in the stone blocks, are either unknown or impossible to take under consideration.

Modeling of Clamps and Dowels

In ancient monuments, iron clamps and dowels exist between the beams of architraves and the stones of walls. In columns, iron dowels were rarely put at the joints, connecting adjacent drums. In such cases, these connectors must be included in the numerical models because they

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 19 Maximum permanent displacements of a column of the Parthenon under the

Aigion, Greece (1995), earthquake amplified to several values of *pga* without and with the imperfections shown in the *left* diagram (Psycharis et al. 2003)

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 20 Displacement at the top of a column of the Olympieion of Athens when the iron dowels at the joints are considered in the analysis (*red line*) and when they are neglected (*blue line*)

affect the response significantly. An example is shown in Fig. 20, in which the displacement of the capital of the column of the Olympieion of Athens is shown: (a) when the two iron dowels of 10 cm² cross section that exist at each joint are considered in the analysis and (b) when they are neglected. The difference in the response of the column, and especially in the amount of permanent deformation, is very large, showing the generally beneficial effect of the dowels on the seismic response. It must be noted, however, that there might be cases in which the prevention of sliding of the upper drums provided by the dowels could be unfavorable to the overall behavior of the column.

In general, dowels should be modeled as nonlinear shear connectors without tensile strength. However, one must have in mind that clamps and dowels were put in inserts carved in the stone blocks and the gap was usually filled with lead. For the dowels placed between the drums of columns, filling the gap with lead was not easy, and, frequently, parts were left without filling. For this reason, it is not usually known whether the dowels are tightly fixed to the drums or small displacements are allowed. This situation introduces an uncertainty in the numerical results, since, if the dowels were loose, the response of the columns would be different.

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 21 Olympieion of Athens: displacement at the top of the E column in the in plane (E–W

direction – *top* diagram) and the out of plane (N–S direction – *bottom* diagram)

It must also be noted that, for large rocking angles, it is possible that a dowel disengages from the upper drum. In that case, the dowel might not be able to reinsert in the mortise during the reversed motion due to the wobbling and the sliding of the drums, blocking thus the proper sitting of the upper drum. In most cases, however, shear dowels are inserted several centimeters in the drums, and, thus, it is not probable that rocking can cause their disengagement, even for strong ground motions.

2D Versus 3D Analysis

For freestanding columns, and despite the symmetry of the column about the vertical axis, there is a significant difference in the response between two-dimensional and three-dimensional analysis. Two-dimensional analysis is unable to capture all the aspects of the real response, mainly the rotation of the drums around the vertical axis due to the simultaneous rocking in two normal

directions. For cylindrical blocks, the pole of rotation continuously changes its position, moving along the perimeter of the base of the drum (wobbling). It is interesting to note that it was observed during shaking table experiments for purely plane excitation that even small disturbances in the direction normal to the plane of rocking could cause significant amplification of the response in that direction (Papantonopoulos et al. 2002).

In general, comparisons between 2D and 3D analyses show that the 2D approach underestimates the response, predicting greater stability.

For systems involving many columns in line or in corner (colonnades), 3D analyses are evidently necessary. In such cases, it has been observed that the end column of each row suffers significant out-of-plane deformation which, for strong earthquake motions, might be significantly larger than the in-plane one. An example is shown in Fig. 21 for a set of two columns of the

Ancient Monuments Under Seismic Actions: Modeling and Analysis, Fig. 22 Stability threshold for the collapse of the freestanding column and the set of two

columns under harmonic excitations: (a) columns of the temple of Apollo; (b) columns of the temple of Zeus (Psycharis et al. 2000)

Olympieion of Athens connected with an architrave. Under a three-dimensional earthquake excitation, the displacement at the top of the east column was much larger in the out-of-plane direction (bottom diagram) than in the in-plane one (top diagram).

Size Effect

Similarly to the single rocking block (see section “Main Features of the Rocking Response”), the size of ancient monuments affects their dynamic response and their vulnerability to earthquakes, with larger structures being more stable than smaller ones. This is shown in Fig. 22, in which the minimum required acceleration amplitude of a harmonic excitation of varying period to cause collapse (stability threshold) is shown for two cases: (a) the columns of the temple of Apollo at Bassae, Greece, of height 5.95 m and (b) the columns of the temple of Zeus at Nemea, Greece, of height 10.33 m (Psycharis et al. 2000). Results are given for the freestanding column and the set of two columns. It is seen that, for the same

period of excitation, significantly larger acceleration is needed to overturn the larger columns of Zeus compared with the smaller columns of Apollo.

Another interesting observation is that the stability threshold of each monument was similar for the freestanding column and the set of two columns. This means that restoration of fallen architraves does not necessarily lead to enhanced stability of the monument against future earthquakes. Figure 22 shows that such restoration of the architraves might be favorable or unfavorable depending on the characteristics of the structure: in the case of Apollo, it was generally unfavorable; in the case of Zeus, it was generally favorable.

It should be mentioned that the above observation concerns the in-plane collapse of the columns (2D analyses). However, shaking table tests on sets of columns connected with architraves in line or in corner have shown that the architrave beams are the most vulnerable parts of monuments, as they are the first pieces that fall down

(in the out-of-plane direction). The collapse of the architraves endangers the stability of the whole monument, since it is possible that they hit the columns during their fall.

Selection of Ground Motions

The earthquake response of ancient monuments is dominated by the rocking of the drums of the columns. As mentioned in section “[Main Features of the Rocking Response](#),” rocking is greatly affected by the predominant period of the excitation. It is evident, therefore, that the vulnerability of a monument depends on the frequency content of the ground motion, with long-period earthquakes being much more dangerous than high-frequency ones. This is shown in Fig. 22, in which the stability threshold decreased exponentially as the period of excitation increased in all cases. Previous analyses (Psycharis et al. 2000) have shown that low-frequency earthquakes force the structure to respond with intensive rocking, whereas high-frequency ones produce significant sliding of the drums, especially at the upper part of the structure.

It is evident that the choice of the earthquakes that will be used in the analyses is very important, as the dynamic response of multi-drum columns and colonnades and the danger of collapse are sensitive to the energy and frequency content of the time history of the input ground motion. Apart from the abovementioned strong effect of the predominant period of the ground motion, the time sequence of the various phases in the record might also be significant. In this sense, it is essential to constrain the selection of the base excitations to what one may call suitable surrogate ground acceleration time histories that could replicate as closely as possible the time histories of past and anticipated earthquakes.

Records must be chosen from past earthquakes which are associated specifically with the tectonics and the seismicity of each region or with earthquakes from other regions of similar tectonics. They may not be always available or in sufficient numbers, but they should not be selected

arbitrarily. The identification of active or potentially active faults, including blind faults, the long-term seismic history of the region and reliable magnitudes as well as regionally representative data on strong ground motions are important parameters that must be considered in this choice. Among the important characteristics of ground motion, time histories to be used in 3D numerical analyses are their maximum velocity and associated period as well as the directivity effects which will be present depending on the proximity of the monuments to a potentially active fault.

From the geological point of view, three independent source parameters are required to describe an earthquake: the fault dimension, the static moment M_0 , and either the mean stress or energy released by faulting or strain energy change. For sites close to the causative fault, the ground motions will show pronounced directivity effects in their ground velocity and displacements. These will appear as long-period amplitude pulses linearly related to the seismic moment. Additionally, the effect of the source mechanism on directivity will be that ground accelerations due to strike-slip faulting will be larger than those due to normal faulting, while ground velocities and displacements will be larger for thrust faulting compared with normal earthquakes.

It is evident, therefore, that the choice of which time histories to include and which to exclude in order to constrain ground motions is an important decision. There is a balance to be struck between being not restrictive enough in the time histories used, leading to unreliable results and hence predictions due to errors and uncertainties, and being too restrictive, which leads to a too small set of time histories and hence nonconclusive results.

Summary

In this chapter the main characteristics of the response of ancient monuments to earthquakes and the difficulties and uncertainties encountered in the analysis, mainly in what regards the values assigned to the parameters of the numerical

model and the selection of surrogate earthquake motions, are presented and discussed. Based on the results of previous studies, the main features of the response can be summarized as follows:

- Owing to rocking and sliding, the response is nonlinear. The nonlinear nature of the response is pronounced even for the simplest case of a rocking single block. In addition, multi-drum columns can rock in various “modes,” which alternate during the response increasing thus the complexity of the problem. The word “mode” denotes the pattern of rocking motion rather than a natural mode in the classical sense, since rocking structures do not possess such modes and periods of oscillation.
- The dynamic behavior is sensitive to even trivial changes in the geometry of the structure or the base-motion characteristics. The sensitivity of the response has been verified experimentally, since “identical” experiments produced significantly different results in some cases. The sensitivity of the response is responsible for the significant out-of-plane motion observed during shaking table experiments for purely planar excitations.
- The vulnerability of the structure greatly depends on the predominant period of the ground motion, with earthquakes containing low-frequency pulses being in general much more dangerous than high-frequency ones. The former force the structure to respond with intensive rocking, whereas the latter produce significant sliding of the drums, especially at the upper part of the structure.
- The size of the structure affects significantly the stability, with bulkier structures being much more stable than smaller ones of the same slenderness.
- Classical monuments are not, in general, vulnerable to earthquakes. However, their stability might have been significantly reduced in the damaged condition that they are found today. Types of damage that might increase their vulnerability to earthquakes include cutoff of drums, displaced drums, inclined columns due to foundation failure, cracks in the stones, etc.

Archeological seismicity; Earthquake archeology; Seismic archeology

Introduction

In 1991 an international conference was held in Athens (Greece), marking the beginning of the modern research field of **archeoseismology**, described as “*the study of ancient earthquakes from the complementary standpoints of their social, cultural, historical and physical effect*” (Stiros and Jones 1996). Besides the term archeoseismology, also the term **seismic archeology** was introduced to emphasize the use of archeological methods in the quest to better understand the effects of earthquakes on historical buildings and archeological remains. Moreover, in analogy with historical seismicity, also the term **archeological seismicity** was suggested.

Archeoseismology can thus be defined as **the interdisciplinary study of ancient earthquakes through evidence in the archeological record, such as destruction layers, structural damage to man-made constructions, cultural piercing features, indications of repairs, abandonment, cultural changes, etc.** Archeoseismology is thus seen as a subdiscipline of paleoseismology with a particular focus on man-made constructions as a potential source of paleoseismological information covering the last few millennia. By doing so, archeoseismology serves objectives proper to seismology and earthquake geology, i.e., parameterizing of earthquakes in an effort to assess the seismic hazard in a region.

Earthquake archeology can be considered as a synonym for archeoseismology. But earthquake archeology can also be seen to serve objectives proper to archeology, i.e., reconstructing human history, in particular attempting to better understand the true impact of earthquakes on human history. The term earthquake archeology can be traced to the Japanese term *jishin kōkogaku*, referring to a research field developed in the mid-1980s in Japan primarily through the initiative of Sangawa Akira, a geomorphologist at the Geological Survey of Japan, focusing on sediment deformation features within archeological contexts (Barnes 2010).

Since the book *Archeoseismology* (Stiros and Jones 1996), a series of special issues of journals has reflected the evolution of the burgeoning discipline over the last two decades towards an ever increasing multidisciplinary discipline (McGuire et al. 2000; Galadini et al. 2006a; Caputo and Pavlides 2008; Sintubin et al. 2010; Silva et al. 2011).

In the current entry, **archeoseismology** is considered as a discipline belonging to the broad research realm of **earthquake sciences**, reflected by a continuum of overlapping and complementary research fields, each focusing a particular source of earthquake data, applying appropriate methods and techniques, and targeting a specific time window. In this respect, archeoseismology bridges the gap between **instrumental** and **historical seismology** on the one side and **paleoseismology** and **earthquake geology** on the other. Archeoseismology focuses on cultural material data spanning the last few millennia. It shares, however, a common goal with the other disciplines, i.e., a better understanding of the earthquake history within a region in an attempt to assess the seismic hazard and mitigate the seismic risk. Most valuable contribution of archeoseismology to seismic hazard assessment is situated in earthquake-prone regions with a long and lasting cultural heritage. Seismic-hazard practitioners are confronted with the problem that the instrumental record is too short (only spanning somewhat over a century) and the historical record too incomplete or even inexistent. By having the potential of determining

earthquake activity over millennial time spans, archeoseismology can indeed extend the archive of earthquakes beyond written sources, thus becoming a legitimate and complementary source of seismic-hazard information.

After a short historical note, a summary of the different types of archeological evidence for ancient earthquakes, commonly used in archeoseismology, is given. Subsequently, the strengths, challenges, and pitfalls of archeoseismology are discussed. Some new developments in archeoseismology will be introduced. In conclusion, some issues and perspectives in archeoseismology are presented.

A Historical Note

In the first volume of the *Palace of Minos*, published in 1921 (Evans 1921), Sir Arthur Evans did not mention earthquakes as a possible cause for the destructions observed during excavation works at the Bronze Age, Minoan site of Knossos (Crete, Greece). In the second volume of the *Palace of Minos*, published in 1928 (Evans 1928), though, tectonic earthquakes became the primary destructive agent, not only leaving a clear marker horizons in the archeological stratigraphy but also causing cultural change as evidenced by discontinuities in ceramic style and architecture. So, what happened in those 7 years that completely changed Evans' thinking?

On 20 April 1922, during the excavation of the “*House of the Sacrificed Oxen*” and the “*House of the Fallen Blocks*” (Fig. 1) at Knossos, Evans experienced an earthquake, leading him to believe that earthquakes of tectonic nature (so not related to the volcanic activity of the Thera/Santorini volcano) may very well have caused damage to the Minoan buildings during the Bronze Age. But only after experiencing the dramatic earthquake that hit the Eastern Mediterranean on 26 June 1926 and caused severe damage in the region of Heraklion, Sir Arthur Evans got convinced that earthquakes are the primary destructive agent responsible for the main stages of destruction observed at Knossos. He developed a seismic archeological stratigraphy,

Archeoseismology, Fig. 1 The “House of the Fallen Blocks” at Knossos, of which the particular context of the massive blocks inspired Sir Arthur Evans that a major earthquake may have been responsible for this damage (cf. Sintubin 2011) © Sintubin

marked with a number of earthquake-related destruction horizons (cf. Jusseret and Sintubin 2013). This work of Sir Arthur Evans can thus indeed be seen as the earliest attempt to introduce earthquakes into archeological contexts.

Evans’ ideas inspired a number of his colleagues around the Eastern Mediterranean, in particular Claude Schaeffer, excavator of the Bronze Age sites of Ugarit (Syria) and Enkomi (Cyprus). In his book *Stratigraphie Comparée et Chronologie de l’Asie Occidentale*, published in 1948 (Schaeffer 1948), Claude Schaeffer went even one step further by correlating archeological destruction layers attributed to earthquakes between Bronze Age archeological sites throughout the Asia Minor, the Caucasus, and the Middle East, setting the stage for the myths of regional earthquake catastrophes. Incorporating modern concepts of seismic storms, the myth of the Late Bronze Age seismic paroxysm around 1200 BC endured to date (e.g., Nur and Cline 2000).

Ever since, earthquakes became all too easy a “*deus ex machina*” to explain to otherwise inexplicable at archeological sites, eventually even to add drama to a site’s history. While skeptical earthquake scientists portrayed this indiscriminate use of earthquakes as neocatastrophism, advocates see the earthquake hypothesis as the simplest solution, referring to Occam’s razor. Therefore, many earthquake scientists still question the basic principles and practices of archeoseismology.

Ancient Earthquakes

Earthquakes that form the subject of archeoseismology are defined as **ancient earthquakes**, i.e., pre-instrumental earthquakes that can only be identified through indirect evidence in the archeological record (e.g., Sagalassos earthquake; cf. Similox-Tohon et al. 2005). Earthquakes that are documented in the historical record may be included if they left marks in the archeological record.

Earthquakes can basically be subdivided in **instrumental** and **pre- or noninstrumental**; the former are instrumentally recorded by seismometers, while the latter are indirectly recorded. The instrumental record covers a little more than a century since the first modern seismometers were designed in the 1890s.

Of **instrumentally recorded earthquakes**, all physical parameters (e.g., magnitude, seismic source, epicenter, duration, intensity distribution, sequence of aftershocks) can be derived. These earthquakes are the main subject of **seismology**. Recent earthquakes can have a major impact on cultural heritage (e.g., 2003 Bam M_W 6.6 earthquake), historical buildings (e.g., 2009 L’Aquila M_W 6.3 earthquake), and/or archeological remains. The latter earthquakes, affecting archeological remains, are though excluded from the field of archeoseismology.

Pre- or noninstrumental earthquakes are only indirectly recorded, in the historical, archeological, and/or geological record. Earthquake parameters that can be derived from these records concern macroseismological parameters, such as intensity, macroseismic epicenter, date, etc.

Historical earthquakes are pre-instrumental earthquakes of which information can be found in all types of historical – written – records (e.g., reports, epigraphy, epitaphs). All this historical information is compiled into earthquake catalogues. Archeoseismology can complement the knowledge with respect to historical earthquakes, when the evidence of specific, well-documented, historical earthquakes (e.g., 365 AD Crete earthquake) on archeological sites is searched for. Also, paleoseismology can add information to better constrain the macroseismological parameters of historical earthquakes.

Prehistorical earthquakes are earthquakes that have no historical record. They can both be ancient earthquakes or paleo-earthquakes.

Paleo-earthquakes, finally, can be interpreted widely, incorporating all prehistorical earthquakes, and even historical earthquakes. In this respect, it becomes synonymous to pre-instrumental earthquakes. One can opt to narrow down the definition of paleo-earthquakes to earthquakes of which evidence is only found in the geological and/or geomorphological record, being subject of **paleoseismology**. These earthquakes are also called **fossil earthquakes**.

Archeological Evidence for Ancient Earthquakes

Archeoseismology calls upon archeological material, ranging from a single occupation horizon within a Holocene stratigraphical context (e.g., Tuttle and Schweig 1995) to a widespread archeological site with monumental buildings (e.g., Similox-Tohon et al. 2006). Methodological developments in archeoseismology is indeed primarily grafted on archeological work in the Eastern Mediterranean and the Middle East, which depends strongly on identifying structural damage to monumental buildings and other cultural remains at archeological sites (e.g., Stiros 1996).

There are two limiting factors to archeoseismological investigations. The first is related to temporal aspects of the archeological record. On the one hand, the time span of occupancy of a site

largely determines the archeoseismological potential of a site (cf. Sintubin and Stewart 2008). It is obvious that the longer the site's occupancy, the higher chances are that a major earthquake has affected the site and left its marks in the archeological record. On the other hand, the archeological record is not evenly distributed through time, to a large extent dependent on socioeconomic, political, and cultural conditions of an ancient society. Secondly, archeoseismological work is limited to archeological sites, which are commonly rather a rare occurrence. There is though a remarkable spatial bias advantageous to archeoseismology, due to a "*fatal attraction*" (Jackson 2006). On the one hand, there appears to be a close relationship between tectonically active environments – thus prone to earthquakes – and ancient civilizations along the southern boundary of the Eurasian Plate (Force and McFadgen 2010). On the other hand, many settlements are founded in seismic landscapes (Michetti and Hancock 1997), thus in the direct proximity of active earthquake faults, as convincingly illustrated by numerous archeological sites throughout the Mediterranean and the Middle East. **Seismic landscapes** are defined as the cumulative geomorphological and stratigraphical effect of signs left on the environment by its past earthquakes over a geologically recent time interval (Michetti and Hancock 1997).

The archeological record can be used in basically three ways to help confront the seismic-hazard threat. First, where archeological relics are displaced, they can be used to find active faults, show in which direction faults slipped during the earthquake(s), and establish comparative fault-slip rates. Second, archeological evidence can date episodes of faulting and shaking. Third, ancient signs of earthquake-related damage, commonly related to ground shaking or ground instabilities (e.g., liquefaction), can be searched for.

Structural Damage Due to Surface Rupturing or Ground Failure

The most obvious and straightforward archeological evidence of fault activity – and thus of earthquakes – are archeological remains that are

Archeoseismology, Fig. 2 The wall of the *Crusader Fortress of Vadum Iacob* (Ateret, Israel) (cf. Marco et al. 1997) is displaced *left* laterally over more than

2 m. The fortress has been built astride the Dead Sea transform plate boundary between the African and Arabian plates © Sintubin

partly displaced due to coseismic surface rupturing on an active fault. As already mentioned, it is definitively not a coincidence that archeological sites are astride active faults.

As cultural piercing features, these **faulted relics** not only serve to identify active faults, but they are also used to determine the type of faulting (normal, reverse, strike slip), the amount of coseismic slip related to a single earthquake, as well as the cumulative fault slip. All these data eventually allow to derive time-averaged fault-slip rates over time spans of centuries to millennia, very comparable to paleoseismological work. The fault-slip rates obtained from an archeological context can subsequently be compared to long-term slip rates from paleoseismological work, enabling the evaluation of potential slip deficits and thus increased seismic hazards.

The most spectacular cases of such faulted relics can be found astride strike-slip faults, in which case there can be no doubt of the tectonic nature of the displacement. Notorious examples are the Crusader Fortress of Vadum Iacob (Israel) (Fig. 2) (cf. Marco et al. 1997) and the Al Harif Roman aqueduct (Syria) (cf. Sbeinati et al. 2010), both located astride the Dead Sea fault, a left-lateral transform plate boundary between the African and Arabian plates. By the way, as long, linear structures, aqueducts are ideal cultural piercing features because chances are they cross more than one fault. Also in extensional settings, giving rise to the typical seismic landscapes of the Mediterranean (from Turkey to Spain), faulted relics are often encountered in archeological sites (Fig. 3) (e.g., Similox-Tohon et al. 2006). In these cases of dip-slip, normal-fault movements,

Archeoseismology, Fig. 3 The mosaic floor of the Roman *Neon Library* at *Sagalassos* (SW Turkey) has been cut by a normal fault, of which a post-363 AD

activity (*terminus post quem*) can be inferred based on the archeological evidence (cf. Similox-Tohon et al. 2006)
© Sintubin

particular caution should be paid to preclude gravitational mass movement that may or may not be seismically triggered (ground failure). Complementary and independent, usually paleoseismological and/or geophysical, evidence to support a tectonic nature of the normal displacement, observed in the faulted relics, is therefore imperative (e.g., Similox-Tohon et al. 2005).

Besides these on-fault effects, numerous off-fault, coseismic ground-failure features can find their way into the archeological record, such as landslides and rockfalls, subsidence and uplift, and liquefaction (see Rodríguez-Pascua et al. 2011 and references therein). The latter sediment-deformation features form the focus of earthquake archeology Japan style (Barnes 2010).

Archeological Destruction Horizons

An **archeological destruction horizon** (destruction layer/destruction deposit) designates a horizon in the archeological stratigraphy showing evidence of sudden destruction caused by human (e.g., war, vandalism) and/or natural agents (e.g., earthquake, storm, flood). These destruction horizons commonly occur on top of “living surfaces,” evidenced by, e.g., in situ broken vases (Fig. 4), buried valuable objects, and/or skeletons of victims. Other criteria are, e.g., burned material, charcoal, collapsed architectural debris, and crushed, toppled objects.

The use of destruction horizons in archeoseismology goes back to the original work of Sir Arthur Evans in Minoan Knossos (Bronze Age Crete), inspiring several generations of archeologists who, often too easily

Archeoseismology, Fig. 4 In situ broken vessels, evidencing a collapse on a “living surface,” as part of a destruction horizon at the Minoan site of *Sissi* (Crete)

that has been attributed to an earthquake in the thirteenth century BC (cf. Jusseret and Sintubin 2012) © J. Driessen

(“*deus ex machina*”), attributed destruction horizons to catastrophic earthquakes. Identifying the true agent, eventually responsible for the destruction horizon, is rarely clear and unambiguous and remains one of the major challenges of archeoseismology.

Destruction horizons, which can with a high degree of certainty be related to ground failure and/or ground shaking caused by an earthquake, are the most appropriate “proxies” for ancient earthquakes in archeological contexts dominated by rubble architecture and associated stratigraphy, such as the Bronze Age civilizations around the Mediterranean and the Harappan civilization in the Indus Valley. In these contexts, no appeal can indeed be made to structural damage evidence on monumental buildings and constructions.

Besides evidencing ancient earthquakes, material (e.g., charcoal) and artifacts (e.g., ceramics, coins) included in the destruction horizons can be used to date episodes of earthquake damage, by means of, e.g., radiocarbon dating, changes in ceramic styles, and numismatics. A major drawback is the temporal resolution of these dating methods with uncertainties ranging from decennia to centuries. On the one hand, this does not allow to pinpoint a destruction horizon to a specific historical earthquake. On the other hand, imprecise age control leads to discrete multiple earthquakes, among which the aftershock sequence of a major earthquake, being amalgamated to “oversized” earthquake catastrophes. Finally, weak time constraints on destruction horizons hamper any reliable territorial correlation of destruction horizons between

Archeoseismology, Fig. 5 Recycling of building material in repair works of a wall at *Susita* (Golan Heights) (cf. Sintubin 2011), possibly after a destructive earthquake © Sintubin

archeological sites, again giving rise to the danger of amalgamating regionally distinct earthquakes.

Other issues concerning destruction horizons are preservation and disturbance. Little is known about the way ancient societies coped with the aftermath of a major earthquake. Earthquake debris may have been cleared from streets and buildings and disposed at particular dumpsites, so that the earthquake destruction horizon is no longer preserved in the archeological record. Valuable and/or victims may have been recovered from the debris, while material may have been reused in rebuilding, leaving behind a highly disturbed earthquake destruction horizon. It is therefore fair to conclude that the visibility of earthquake destruction in the archeological stratigraphy is rather dependent on social factors than on physical parameters (cf. Jusseret and Sintubin 2012).

Finally, other archeological evidences, such as repairs, recycling of building materials (Fig. 5), complete or partial abandonment, and architectural and/or cultural changes, can further contribute to the identification of ancient earthquakes.

Structural Damage Due to Ground Shaking and Ground Motion

A third type of earthquake evidence in the archeological record are typical **strain structures in the building fabric** that are primarily caused by coseismic ground shaking and ground motion. These earthquake-related damage features are most conspicuous on monumental buildings and constructions, such as temples, fountains, theaters, basilicas, pavements, columns, statues, aqueducts, etc.

A first systematic inventory of possible earthquake-related damage typologies has been

introduced by Stiros (1996). Currently all these potential earthquake indicators are compiled in a comprehensive classification of **Earthquake Archeological Effects** (EAEs) (Rodríguez-Pascua et al. 2011), completely based on the guidelines of the Earthquake Environmental Effects (EEEs) that are used in the framework of the macroseismic Environmental Seismic Intensity scale (ESI2007, Michetti et al. 2007). These guidelines prescribe the difference between “primary (direct) effects” and “secondary (indirect) effects.” In archeological contexts, the latter effects of which evidence can be found in the archeological record and in particular destruction horizons, reflect the way an ancient community copes with the consequences of an earthquake affecting their settlement. Besides the on-fault (e.g., surface rupturing) and off-fault (e.g., liquefaction) geological effects, the former effects are specifically recorded in strain structures in the building fabric.

Different types of strain structures can, on the one hand, be generated by coseismic ground motion: folded and fractured pavement; shock breakouts in flagstone pavement; tilted, rotated, displaced, and bent walls, etc. On the other hand, other types of strain structures in the building fabric can be generated by coseismic ground shaking: penetrative fractures in masonry walls and columns; rotated, displaced, and ejected masonry blocks in walls; rotated and displaced drums in columns (Fig. 6); dropped keystones in arches (Fig. 7); rotated steps in stairways; collapsed stairways; folded curbs; domino-type collapsed walls and columns; directional collapse of columns; collapsed vaults; impact markings on pavements; dipping broken corners and chipping marks; U-shaped gaps in walls, etc.

The obvious difficulty with these building fabric effects is that it remains very challenging to distinguish between damage caused by an earthquake and damage caused by other destructive physical or human agents, such as natural failure of the foundations, vandalism, or warfare. Moreover, standing or partially standing buildings and constructions at archeological sites in earthquake-prone regions most probably experienced ground shaking from numerous – minor to

Archeoseismology, Fig. 6 Displaced drums of a column in the *Temple of Aphrodite* in the Roman city of *Aphrodisias* (SW Turkey), as a potential earthquake archeological effect © Sintubin

moderate to major – earthquakes over the life span of the structure, which makes it nearly impossible to attribute specific building fabric effects to a particular earthquake. Working with these damage typologies, possibly indicative of ground shaking, the investigator has to be very cautious not to “overinterpret” the potential earthquake archeological effects. Uncertainties, inherent to any archeologically based earthquake hypothesis, should moreover be assessed properly (cf. Sintubin and Stewart 2008).

Parameterization of Ancient Earthquakes

Besides the inherent ambiguities and uncertainties of archeological earthquake evidence, primarily resulting from the difficulty to

Archeoseismology, Fig. 7 A dropped keystone in the *Roman Baths at Sagalassos* (SW Turkey), interpreted as a potential earthquake archeological effect (cf. Similox-Tohon et al. 2006) © Sintubin

irrefutably distinguish between damage caused by earthquakes and that caused by other natural agents or human intervention, the main issue archeoseismology is confronted with is the question how earthquake evidence in destruction horizons and/or disturbed buildings can be meaningfully translated into physical earthquake parameters, such as intensity, magnitude, distance to epicenter, date of earthquake, ground acceleration, etc. Ultimately, because the limitations of the archeoseismological record are all too obvious when it comes to claiming its potential role in seismic-hazard studies, it all boils down to the question what the true added value is of archeoseismology.

In Search of a Shared Protocol and Standardized Methodology

Archeoseismology's greatest challenge – and its foremost attraction – remains to date the

integration of principles and practices of a very wide range of sciences, from history, anthropology, archeology and sociology, over geology, geomorphology, geophysics, and seismology to architecture and structural engineering. Arguably the principle difficulty in archeoseismology is the lack of a shared protocol and of a rigorous and transparent standardized methodology (cf. Sintubin and Stewart 2008 and references therein).

Through the years, different, primarily qualitative, archeoseismological schemes have been proposed, consisting of points of interest (Karcz and Kafri 1978; Rapp 1986; Nikonov 1988; Stiros 1996), key research questions (Guidoboni 1996), or flow charts (Galadini et al. 2006b) that ought to be considered during excavation works at an archeological site by collaborative teams of seismologists, geologists, archeologists, etc. (see Sintubin and Stewart 2008 for synthetic

overview of archeoseismological schemes). More recently, the comprehensive classification of earthquake archaeological effects (EAEs) (Rodríguez-Pascua et al. 2011) pursues the integration of archeoseismological evidence in the framework of the macroseismic Environmental Seismic Intensity scale (ESI2007, Michetti et al. 2007). These efforts to develop a shared protocol, however, are commonly designed from within a single scientific discipline.

Most of these schemes have been grafted onto the archeological work in the Mediterranean and the Middle East, strongly relying on strain structures in the building fabric (e.g., Stiros 1996). More quantitative approaches evaluate the probability of the occurrence of a proposed ancient earthquake by using a feasibility matrix for archeoseismological findings (Hinzen 2005) or assess the degree of certainty to which an archeological site has recorded an ancient earthquake by using a logic-tree formalism (Sintubin and Stewart 2008).

In recent years, a clear shift in perspective, from qualitative to more quantitative and multidisciplinary approaches, trying to integrate earthquake evidence from different perspectives (e.g., archeoseismology, geophysics, paleoseismology, geomorphology, geology), has definitively proven a major advancement in the discipline, supporting the reliability of the archeoseismological evidence (e.g., Similox-Tohon et al. 2006).

Because of the wide variety of disciplines involved, from the humanities and the social, natural, and engineering sciences, it seems, though, nearly inevitable that all practitioners who look at earthquake evidence in the archeological record will keep pursuing different objectives. The historian may want to know if an earthquake had any effect on the political, social, or military balance in a region. The engineer may be concerned about mitigating the seismic threat to our cultural and architectural heritage, while the seismologists are attempting to complete the historical catalogue of earthquakes and their physical parameters. Finding a balance between all these interests will also in the future remain archeoseismology's greatest challenge.

Ancient Seismoscopes

For assessing the seismic hazard of a region, an accurate catalogue of earthquakes and their physical parameters is imperative. Seismic-hazard practitioners need exact dates, magnitudes, source areas, etc. of past earthquakes. Taking into account the incompleteness of the archeological record, its limited spatial and temporal resolution, and the uncertainties inherent to archeological earthquake evidence, the skepticism with respect to the applicability of archeoseismology in **seismic-hazard studies** is indeed legitimate (cf. Sintubin 2011).

Some common pitfalls keep adding to the seismologist's skepticism. There is the **preservation problem**. The archeological record is not evenly distributed through time. Ancient history consists of long periods of cultural, social, and political stability and flourishing economies, during which any sign of earthquake is most probably expertly covered up. In contrast, during intervening, short periods of social and political upheaval, and economic crisis, signs of destructive earthquakes may be left extant, primarily because there is no impetus or funds to fully recover from the earthquake disaster. Only then, the earthquake leaves its marks in the archeological record, giving rise to an observational bias that focuses on periods of upheaval, destruction, abandonment, etc.

Another danger exists that "anomalous" earthquake catastrophes, supposedly proven by archeologists, are used uncritically in seismic-hazard assessments as "real" events (Ambraseys et al. 2002). Moreover, confronting the archeoseismological evidence, commonly poorly constrained in time and space, with the evenly incomplete and sometimes poorly constrained historical earthquake catalogues, may carry the risk of an arbitrary correlation, inevitably leading to **circular reasoning** (Rucker and Niemi 2010). When archeologists identify a destruction horizon as caused by an earthquake and consult existing earthquake catalogues to assign a date to the particular earthquake-related destruction horizon, the risk exists that historical seismologists add this particular archeological site to the catalogue as evidence

for that particular historical earthquake. This overreliance on historical catalogues clearly corrupts the usefulness of archeoseismology and should therefore be omitted from archeoseismological practices.

Given all these pitfalls, it becomes apparent that archeoseismological investigations should indeed not start from a seismological perspective but from the archeological earthquake evidence itself, with all its inherent limitations and uncertainties. Rather than simply complementing earthquake catalogues with potentially highly conjectural, ancient earthquakes, archeological sites may have the potential of becoming testing grounds to quantitatively assess site-specific ground effects. In this respect, archeological sites become **ancient seismoscopes** that can be used strategically to examine specific earthquake scenarios in a region (cf. Sintubin 2011). Archeological sites, especially those with a long and lasting history, do have the potential to have recorded the effects of a major earthquake. A quantitative assessment of the ground motions on archeological sites may indeed hold the eventuality to have narrowed down macroseismic parameters associated with the maximum credible earthquake in the region, irrespective of the time of occurrence, the magnitude, the seismic source, etc. With such an approach, archeoseismology enters in the logics of scenario-based, deterministic seismic risk assessment.

New Developments in Archeoseismology

This tendency towards a more standardized and quantitative approach of potential archeological earthquake evidence in archeological sites is fully exemplified in the rapid advances in **quantitative archeoseismology** (cf. Hinzen et al. 2011 and references therein). This recent development in archeoseismology primarily focuses on monumental architecture, the classical field of application of archeoseismology since its beginning (cf. Stiros 1996). Quantitative archeoseismology firstly applies modern techniques, such as 3D laser scanning (e.g., ground-based LIDAR), to obtain a three-dimensional

Archeoseismology, Fig. 8 Perfectly aligned *toppled columns* at *Susita* (Golan Heights), classically interpreted as indicative for the direction of strong ground motion caused by a major earthquake. Such earthquake hypothesis does not pass the test of scenario-based ground motion simulations (cf. Hinzen et al. 2011) © Sintubin

structural model of the archeological damaged building or structure, allowing the construction of a very precise structural damage inventory. Using earthquake engineering models, the dynamic behavior of the ancient structure can be evaluated. Subsequently, scenario-based earthquake ground motion simulations enable testing a realistic earthquake hypothesis to explain the damage observed. This approach has already lead to the conclusion that in a number of cases, alternative, natural, or anthropogenic causes are more probable than the seismic cause that has originally been considered. Moreover, “classical” damage typologies attributed to earthquake-related ground motions, such as the perfectly aligned toppled columns (Fig. 8), could not be validated, even adding to the skepticism towards “classical” archeoseismological practices.

Besides this added value of quantitative archeoseismology with respect to monumental architecture, also the value of rubble architecture and associated destruction horizons get again particular interest in a more quantitative, **integrated territorial approach** that starts from the specific seismotectonic context and the empirical ground-motion relationships of potential earthquake sources and focuses on well-documented, high-visibility archeological contexts, characterized by very rapid ceramic change (~100-year time window) (cf. Jusseret and Sintubin 2012).

Issues and Perspectives in Archeoseismology

Archeoseismology will always be plagued by the ambiguities inherent to the archeological record of ancient earthquakes. In this respect, archeoseismology may very well never be able to deliver reliable and conclusive earthquake evidence that is needed to improve the **assessment of the seismic hazard** in a region. New developments towards more integrated, multidisciplinary approaches as well as quantitative archeoseismology will allow, though, that the potential of archeological sites as **ancient seismoscopes** is fully developed in the future.

The fact that the archeological visibility of earthquakes may be strongly biased towards the relatively short but commonly well-documented (e.g., rapid changes in ceramic styles) periods in a society's history of social, political, and/or economic turmoil opens unique perspectives for archeoseismological research. Preservation of archeological earthquake evidence may indeed rather be related to societal factors than to physical aspects of the ancient earthquakes. Ultimately, the relatively undisturbed, extant archeological record of earthquakes can tell us more about past societies and their attitude to physical disasters (cf. Jusseret and Sintubin 2012). A better appreciation of the complex way by which our ancestors responded to damaging earthquakes might

indeed shed light on the societal factors defining the resilience or vulnerability of past societies. Eventually, by highlighting how our ancestors coped with earthquake disasters, archeoseismology could find new aspirations in establishing local **earthquake cultures** in earthquake-prone regions (cf. Sintubin et al. 2008), possibly providing a substantial contribution to the **mitigation of the earthquake risk**, by improving earthquake risk literacy and awareness.

Summary

Archeoseismology is the interdisciplinary study of pre-instrumental, **ancient earthquakes** through indirect evidence in the archeological record. As a burgeoning discipline within the broad research realm of **earthquake sciences**, archeoseismology bridges the gap between **instrumental** and **historical seismology** on the one side and **paleoseismology** and **earthquake geology** on the other.

The archeological record can be used in basically three ways in the identification and characterization of ancient earthquakes. The most obvious and straightforward archeological evidence of fault activity are archeological remains that are partly displaced due to coseismic surface rupturing on an active fault. As cultural piercing features, these **faulted relics** can be used to determine the type of faulting, the amount of coseismic slip, as well as the cumulative fault slip. Within the archeological stratigraphy, particular horizons can be designated to sudden destruction caused by human and/or natural agents. If the **archeological destruction horizons** can be attributed to an earthquake with a high degree of certainty, material included in the destruction horizons can be used to date episodes of earthquake damage. Destruction horizons are the most useful “proxy” for ancient earthquakes in archeological contexts dominated by rubble architecture and associated stratigraphy. A third type of earthquake evidence in the

archeological record are typical **strain structures in the building fabric** that are primarily caused by coseismic ground shaking and ground motion. These earthquake-related damage features are most conspicuous on monumental buildings and man-made constructions.

Archeoseismology will always be plagued by the ambiguities and uncertainties inherent to the archeological earthquake evidence, primarily resulting from the difficulty to irrefutably distinguish between damage caused by earthquakes and that caused by other natural or human agents. In this respect, archeoseismology may very well never be able to deliver reliable and conclusive earthquake evidence that is needed to improve the assessment of the seismic hazard in a region. Archeological sites have though the potential of becoming testing grounds to quantitatively assess site-specific ground effects. As **ancient seismoscopes**, archeological sites may hold the eventuality to have narrowed down macroseismic parameters associated with the maximum credible earthquake, irrespective of the time of occurrence and the physical parameters of the earthquake. Finally, preservation of archeological earthquake evidence may rather be related to societal factors than to physical parameters. In this respect, the relatively undisturbed archeological record of ancient earthquakes can tell us more about past societies and their attitude to physical disasters.

Artificial Offshore Seismic Sources

Wolfgang Rabbel and Dennis Wilken
Institute of Geosciences, University of Kiel,
Kiel, Germany

Synonyms

Marine seismic sources; Seismic energy sources

Introduction

Artificial Offshore Seismic Sources are instruments that are used for generating short-duration pressure pulses in the marine water column, usually with constant repetition rate. They provide the acoustic energy for marine seismic surveys. Marine seismic surveys are performed in order to image geological structure (layers and faults) beneath the seafloor and to characterize rocks and rock strength in terms of seismic wave velocity or dynamic elastic constants. Therefore, short pressure pulses are applied to the water column that travel as acoustic waves down to the sea bottom where they are converted into seismic body and interface waves (elastic waves). These seismic waves penetrate deeper into the underground and are partially reflected at geological interfaces and/or refracted back to the surface (Fig. 1, right). This returning part of the wave field is recorded either at the seafloor with seismographs or in the water column with hydroacoustic receivers. In order to allow for profiling both seismic source and receivers are towed behind a vessel carrying out repeated measurements while moving forward. The technique of marine seismic has been developed and improved continuously since the late 1940s. This entry provides an overview of the purpose and principles marine seismic sources. More detailed information can be found, for example, in Jones (1999) and Meunier (2011).

General Considerations

The goal of marine seismic reflection surveys is to image geological structure down to a predefined target depth at highest possible resolution. Therefore, the pressure pulses generated by a marine seismic source are usually designed to have a sharp onset and short duration (some to some 10 ms; exception marine vibrator source) corresponding to a broadest possible frequency spectrum. The short duration, respective large bandwidth, is necessary to enable distinguishing of reflections (echoes) arriving at the receivers subsequently from interfaces at increasing depths. Seismic wave propagation is affected by absorption that leads to a notable continuous decrease of amplitudes starting from the high-frequency end of the spectrum. Therefore, penetration depth increases with decreasing signal frequency. While it propagates, the wave front widens and signal amplitudes decrease accordingly (“geometrical spreading”). This effect needs to be compensated for by increasing the initial strength of the pressure pulse in order to keep reflected signals of deep horizons detectable. Finally, in order to obtain a reliable depth section, the measured profiles have to be sampled spatially with a sufficiently high density realized by repeating the measurements while the vessel is moving. This implies that the marine seismic source needs to be reloadable within a certain time interval depending on the velocity of the ship. Typical repetition intervals are between 0.5 up to some 10 s. The target range relevant for seismic exploration – for example in earthquake engineering – may extend from near-seafloor layering down to several kilometers depth, for example, in order to detect and trace deep reaching fault systems. Correspondingly, different sorts of seismic sources are in use, each accounting for different target depth or infrastructure related situations (Table 1).

Types of Marine Seismic Sources and Their Key Principles

Airguns and GI-guns

Airguns or G-(Generator)-Guns generate an acoustic impulse by releasing a high pressure air

GI-Gun

Sparker

Boomer

A

Artificial Offshore Seismic Sources, Fig. 1 *Right:* Principle of marine seismic data acquisition; pulse-like seismic waves travel through geological layers and are reflected back to the surface at interfaces where density

or propagation velocity change; wave propagation paths indicated by rays (*black lines*). *Left:* examples of seismic sources for near-surface prospecting; from *top to bottom*: Airgun (GI-gun), Sparker, Boomer

bubble underwater. The radiation pattern of the airgun source corresponds to an acoustic dipole because an image-source mirrored at the water surface has to be considered in order to account for the free-surface condition. It causes a so-called ghost reflection following the primary pulse with negative polarity and a time delay depending on source depth. While moving to the sea surface, the generated bubble oscillates around the equilibrium of air- and hydrostatic water pressure with a natural period T . T depends on the energy of the injected air E , the confining hydrostatic pressure P of the water column, and the fluid density d according to the Rayleigh-Willis formula $T \approx 1.14d^{1/2} P^{-5/6} E^{1/3}$. This oscillation generates an undesired lengthening of the seismic signal. In order to overcome the

bubble oscillation, GI-(Generator Injector)-Guns are very common that inject a second air pulse to collapse the initial bubble before it starts to oscillate. G-Guns and GI-Guns can be mounted in arrays to enhance the signal amplitude and, when fired with time offsets, to modulate the shape of the signal.

The generated frequency content mainly depends on the volume of the airgun chamber, the assigned pressure, and the tow depth.

Water Guns

A water gun is a pneumatic seismic source operated by compressed air, too. The air is used to drive a piston pressing water from a chamber inside the gun into the water column. The seismic impulse is generated by the implosion of a cavity

Artificial Offshore Seismic Sources, Table 1 Technical data and properties of typical marine seismic sources. The given value of structural resolution corresponds to a quarter wavelength at 1,600 m/s wave speed

Source type	Chamber volume (l)	Energy per pulse (J) / pressure (dB reference 1 μ Pat 1 m)	Spectral width (Hz)	Main frequency (Hz)	Typical exploration depths	Resolution at main frequency (m)	Power supply unit
Airgun	0.2–32	~10 kJ/170–230 dB	—	10–200	Some 100 m to some km	2–40	Compressor
GI Gun	0.4–4	~10 kJ/170–230 dB	—	50–200	Some 100 m to some km	2–8	Compressor
Water Gun	0.2–2	~30 kJ	—	50–1,000	Some 100 m to some km	0.4–8	Compressor
Sparker	—	300–2,400 J	100–3 k	~1,500	Upto ~200 m	0.25	Capacitor bank
Boomer	—	300–700 J	500–4 k	~3,000	Upto ~100 m	0.15	Capacitor bank
Pinger	—	~100 J	2 k–150 k	—	Upto ~10 m	0.2–0.03	Electrical amplifier
Vibro source	—	Some 10 kW times sweep length (s)	6–100	—	Some 100 m to some km	4–100	Electrical current

created behind the expelled water. It is free of bubble oscillations and contains higher frequencies than typically generated by airguns.

Sparker

The sparker source generates an acoustic impulse by a high-voltage spark discharge between two electrodes in the water. The spark consists of a high-pressure plasma whose expansion and collapse generates the acoustic peak. The high voltage needed to generate such a plasma is stored in a bank of capacitors, which is reloaded for each shot. Sparkers can be used at different energy levels, depending on the capacitor bank. Commonly sparkers are used in arrays to enhance the signal amplitude and to maintain the signal shape which usually changes because the electrodes tend to tip-off during usage. Sparkers can be applied in brackish water and seawater.

Boomer

Boomers are also based on combining electromagnetic and mechanical principles. Similar to the sparker case, electric charges are assembled in a bank of capacitors releasing a high-voltage

pulse to the source. The discharge is led through a flat coil inside the source body. From below an aluminum plate is pressed against the coil by springs. The magnetic field of the coil induces eddy currents inside this plate. These currents produce magnetic fields that repel the plate from the coil (Lenz's law). The spring then moves the plate back, leaving a collapsing cavitation volume that generates the acoustic impulse.

Pinger

Sediment echo sounders (SES) use piezoelectric "pingers" as electroacoustic converters.

Some materials (especially crystalline) tend to show electromechanical properties which means that the material is stretched when voltage is applied. Closely packed piezoelectric crystals are very effective electroacoustic converters and can be used as acoustic sources.

These pingers are applied as single point sources or – even more often – in arrays which enable, when used with time offsets, a modulation of the radiation pattern of the source. Alternative developments are based on the parametric nonlinearity effect to enhance the acoustic efficiency and the stability of the signal.

Marine Vibrator

Marine vibrator sources are basically volumetrically oscillating shells that transmit a chirp signal (“sweep”) to the water column. The chirp is linearly modulated in frequency and lasts typically several seconds. Seismic reflections can only be recognized after the records were cross-correlated with the source signal. This concept was adopted from the onshore VibroseisTM method (e.g., Sheriff and Geldart 1995). The shells are constructed flexible or otherwise expandable; the oscillations are driven by hydraulic, magnetostrictive, or electromagnetic devices placed inside (e.g., Tenghamn 2006; Meunier 2011). Like airguns and water guns, marine vibrators can be combined to form arrays in order to improve energy output and radiation characteristics. They work in a similar frequency range as airguns and release similar seismic energy in total. However, since they provide energy at lower rate over a much longer time interval they are causing less environmental impact than the impulsive source that release energy within some 10 ms. Since the vessel moves significantly while the source is active, Doppler effects occur in the records that need to be corrected in during data processing. For near-surface investigations, Vibroseis-type chirps can be generated through low-energy piezoelectric transducers. However, marine vibrators for deep (km-scale) sounding are still under development.

Summary

Artificial Offshore Seismic Sources are instruments emitting sound signals for marine seismic surveys that are performed for investigating offshore geological structure. Functional principles of marine seismic source depend on the required energy and frequency content of the signals, including piezoelectric and high-pressure air pulsers as low and high energy end members. The structural resolution of the seismic images of geological layering ranges from some 10 cm to some 10 m depending on the depth of the target horizons and the seismic sources applied.

Assessment and Strengthening of Partitions in Buildings

Christis Z. Chrysostomou

Department of Civil Engineering and Geomatics,
Cyprus University of Technology, Limassol,
Cyprus

Synonyms

Infills; Infill walls; Masonry infills; Reinforced concrete infills

Introduction

Partitions in buildings are necessary architectural features that separate spaces in order to facilitate various functions that are required depending on the use of a building. These partitions in modern structures can be lightweight, for example, in case that they are used to subdivide office spaces, or can be heavy masonry partitions that are used mainly in reinforced concrete structures to subdivide the plan area of a building into various rooms. In the latter case, these are mostly built within the frame of the structure filling the gap, and they are therefore called infills or infill walls. Depending on the type of the material that is used to construct them, they can be called masonry infills or reinforced concrete (RC) infills.

Infill walls have attracted the attention of many researchers since the early 1950s, and much work has been undertaken to study their behavior and interaction with the surrounding

frames. In addition, efforts have been made to utilize infill walls as a means of producing economic designs by reducing the sizes of the members of the bounding frames.

A large number of researchers have studied the behavior of infilled frames. It is evident from their studies that infill walls can provide both an economic and practical means for the lateral stability of framed structures and a viable alternative for retrofitting existing structures to resist seismic, wind, and blast loads. Despite this, there is reluctance from the engineering community to use this structural system widely and treat infill walls as structural elements.

Therefore, although the subject of infilled frames has been studied for more than 60 years, there are still no definitive answers either about their behavior and interaction with the bounding frame or about the estimation of their stiffness and strength. Some problems that make it difficult for practicing engineers to use infill walls as structural elements are the inherent nonlinearity, the high degree of variability, and the inherent degradability of infill walls. The fact that infill walls exhibit completely different in-plane and out-of-plane behavior makes the problem even more difficult to tackle. This reveals the difficulties associated with this problem and the need for more research to answer these long-standing questions.

Nevertheless, the presence of infill walls has shown that in most cases they have beneficial effects on the behavior of structures during earthquakes and have contributed in the prevention of collapse of many structures. It is therefore for this reason that efforts have been made to use engineered infills to retrofit existing seismic-deficient buildings, since they present an economically viable solution.

In this entry, the in-plane behavior and in-plane failure modes of infilled frames are presented. Then, macro- and micromodels for infill walls are presented followed by the results of experimental investigations for the replacement of masonry infill walls with reinforced concrete infills, as an economically viable method for retrofitting existing structures. Finally, methods

for strengthening existing partition walls are presented.

Behavior of Partitions

The modeling of the behavior of infilled frames under lateral loading (and mainly earthquake-induced loads) is a complex issue because these structures exhibit a highly nonlinear response due to the interaction between the masonry infill panel and the surrounding frame. This results to several modes of failure, each of which has a different failure load, and hence a different ultimate capacity and overall behavior.

At moderate loading levels, the infill of a non-integral infilled frame separates from the surrounding frame and the infill acts as a diagonal strut (Fig. 1). As the racking load is increased, failure occurs eventually in either the frame or the infill. The usual mode of frame failure results from tension in the windward column or from shearing in the column or beams or plastic hinging in columns or beams; however, if the frame strength is sufficient enough to prevent its failure by one of these modes, the increasing racking load eventually produces failure of the infill. In the most common situations, the in-plane lateral load applied at one of the top corners is resisted by a truss formed by the loaded column and the infill along the diagonal connecting the loaded corner and the opposite bottom corner. The state of stress in the infill gives rise to a principal compressive stress along the diagonal and a principal tensile stress in the perpendicular direction. If the infill is made of concrete, successive failures, initially by cracking along the compression diagonal and then by crushing near one of the loaded corners or by crushing alone, will lead to collapse; if the infill is made of brick masonry, an alternative possibility of shearing failure along the mortar planes may arise (Fig. 1).

Based on both experimental and analytical results during the last five decades, different failure modes of masonry-infilled frames were proposed that can be classified into five distinct modes given below:

Assessment and Strengthening of Partitions in Buildings, Fig. 1 Failure modes of non-integral infilled frames: (a) Corner crushing (CC) and diagonal

compression (DK) modes. (b) Sliding shear (SS), frame failure (FF), and diagonal cracking (DK) modes (Asteris et al. 2011 with permission from ASCE)

1. The corner crushing (CC) mode, which represents crushing of the infill in at least one of its loaded corners, as shown in Fig. 1a. This mode is usually associated with infilled frames consisting of a weak masonry infill panel surrounded by a frame with weak joints and strong members (Mehrabi and Shing 1997; El-Dakhakhni 2002; Ghosh and Amde 2002; El-Dakhakhni et al. 2003).
2. The diagonal compression (DC) mode, which represents crushing of the infill within its central region, as shown in Fig. 1a. This mode is associated with a relatively slender infill, where failure results from out-of-plane buckling of the infill.
3. The sliding shear (SS) mode, which represents horizontal sliding failure through bed joints of a masonry infill, as shown in Fig. 1b. This mode is associated with weak mortar joints in the infill and a strong frame.
4. The diagonal cracking (DK) mode, which is seen in the form of a crack across the compressed diagonal of the infill panel and often takes place with simultaneous initiation of the SS mode, as shown in Fig. 1b. This mode is associated with a weak frame or a frame with weak joints and strong members infilled with a rather strong infill (Mehrabi and Shing 1997; El-Dakhakhni 2002).
5. The frame failure (FF) mode, which is seen in the form of plastic hinges developing in the columns or the beam-column connections, as shown in Fig. 1b. This mode is associated with a weak frame or a frame with weak joints and strong members infilled with a rather strong infill.

Ghosh and Amde (2002), based on the finite element method and including interface elements at the frame-infill interface, confirmed the order of occurrence of the above five distinct failure modes. Of the five modes, only the CC and SS modes are of practical importance (Comité Euro-International du Béton CEB 1996), since most infills are not slender (El-Dakhakhni et al. 2003) and therefore the second mode (DC) is not favored. The fourth mode (DK) should not be considered as a failure mode, due to the post-cracking capacity of the infill to carry additional load. The fifth mode (FF) relates to the failure of the frame, and it is particularly important when examining existing structures, which in many cases exhibit frame weakness. It should be noted that these failure modes are only seen/applicable to the case of infill walls without openings on the diagonal of the infill panel.

Kappos and Ellul (2000), based on an analytical study of the seismic performance of masonry-infilled RC-framed structures, found that taking into account the infill in the analysis resulted in

an increase in stiffness as much as 440 %. It is clear that, depending on the spectral characteristics of the design earthquake, the dynamic behavior of the two systems dealt with by the author (bare vs. infilled frame) can be dramatically different. They also presented a very useful global picture of the seismic performance of the studied infill frames by referring to the energy dissipated by each component of the structural system. It is clear that at the serviceability level, over 95 % of the energy dissipation is taking place in the infill walls (subsequent to their cracking), whereas at higher levels, the RC members start making a significant contribution. This is a clear verification of the fact that masonry infill walls act as a first line of defense in a structure subjected to earthquake load, while the RC-frame system is crucial for the performance of the structure to stronger excitations (beyond the design earthquake).

The quantification of the in-plane properties of non-integral infilled frames and the prediction of the failure modes is a rather cumbersome task even when the load is applied monotonically. The problem becomes even more difficult when a dynamic load is applied, since the hysteretic behavior of the materials and their deterioration with the cyclic loading should be taken into consideration. Chrysostomou and Asteris (2012) discuss these issues and present methods for the determination of the in-plane stiffness, strength, and deformation capacity of infills along with the results of a parametric study that compares these methods and checks them against experimental results whenever possible. Based on the above material, recommendations are made for the in-plane material properties, failure modes, strength and stiffness, as well as deformation characteristics, of infilled frames.

Modeling of Partitions

In order for engineers to be able to use infills as an engineering element, a reliable mathematical model needs to be developed that simulates the combined behavior of the infill partition and the bounding frame. As explained in the previous section, the behavior of infilled frames is rather complex and it depends on a large number of

parameters. Therefore, for the mathematical model to accurately simulate the behavior of infilled frames, it should take into consideration all these parameters.

The models for infills can be subdivided into macro- and micromodels. In the former, simple models are developed that are simulating the overall global behavior of infilled frames, while in the latter, surface or solid finite elements are used along with interface ones that simulate both the local and global behavior of both the infills and the bounding frames and their interaction. In the following two sections macro- and micromodels are presented.

Macromodeling

Since the first attempts to model the response of the composite infilled frame structures, experimental and conceptual observations have indicated that a diagonal strut with appropriate geometrical and mechanical characteristics could possibly provide a solution to the problem. Early research on the in-plane behavior of infilled frame structures undertaken at the Building Research Station, Watford (later renamed Building Research Establishment and now simply BRE), in the 1950s served as an early insight into this behavior and confirmed its highly indeterminate nature in terms solely of the normal parameters of design. On the basis of these few tests, a purely empirical interaction formula was later tentatively suggested for use in the design of tall framed buildings.

Diagonal Strut Model

In the early 1960s, Polyakov suggested the possibility of considering the effect of the infilling in each panel as equivalent to diagonal bracing, and this suggestion was later adopted by Holmes, who replaced the infill by an equivalent pin-jointed diagonal strut made of the same material and having the same thickness as the infill panel and a width defined by

$$\frac{w}{d} = \frac{1}{3} \quad (1)$$

where d is the diagonal length of the masonry panel. The “one-third” rule was suggested as

being applicable irrespective of the relative stiffness of the frame and the infill. One year later, Stafford Smith, based on experimental data from a large series of tests using masonry-infilled steel frames, found that the ratio w/d varied from 0.10 to 0.25. On the second half of the 1960s, Stafford Smith and his associates using additional experimental data related the width of the equivalent diagonal strut to the infill-frame contact lengths using an analytical equation, which has been adapted from the equation of the length of contact of a free beam on an elastic foundation subjected to a concentrated load. They proposed the evaluation of the equivalent width λ_h as a function of the relative panel-to-frame-stiffness parameter, in terms of

$$\lambda_h = h \sqrt[4]{\frac{E_w t_w \sin 2\theta}{4EI h_w}} \quad (2)$$

where E_w is the modulus of elasticity of the masonry panel, EI is the flexural rigidity of the columns, t_w is the thickness of the infill panel and equivalent strut, h is the column height between centerlines of beams, h_w is the height of infill panel, and θ is the angle, whose tangent is the infill height-to-length aspect ratio, being equal to

$$\theta = \tan^{-1} \left(\frac{h_w}{L_w} \right) \quad (3)$$

in which L_w is the length of infill panel (all the above parameters are explained in Fig. 2).

The use of this equation to seismic design is recommended for a lateral force level up to 50 % of the ultimate capacity.

Based on experimental and analytical data, Mainstone proposed an empirical equation for the calculation of the equivalent strut width, given by

$$\frac{w}{d} = 0.16 \lambda_h^{-0.3} \quad (4)$$

Mainstone and Weeks and Mainstone, also based on experimental and analytical data, proposed a

Assessment and Strengthening of Partitions in Buildings, Fig. 2 Definitions for the equivalent diagonal strut (Asteris et al. 2011 with permission from ASCE)

slightly modified empirical equation for the calculation of the equivalent strut width:

$$\frac{w}{d} = 0.175 \lambda_h^{-0.4} \quad (5)$$

This formula was included in FEMA-274 for the analysis and rehabilitation of buildings as well as in FEMA-306, as it has been proven to be the most popular over the years. Although this equation is accepted by the majority of researchers dealing with the analysis of infilled frames, several variations were presented by various researchers trying to improve its applicability. A discussion and comparison of these proposals as well as references to the work of the various researchers mentioned above is given by Chrysostomou and Asteris (2012), and Asteris et al. (2011).

Multiple-Strut Models

In the last two decades, it became clear that one single-strut element is unable to model the complex behavior of the infilled frames. The bending moments and shear forces in the frame members cannot be adequately represented using a single diagonal strut connecting the two loaded corners.

Assessment and Strengthening of Partitions in Buildings,
Fig. 3 Six-strut model for masonry infill panel in frame structures
 (Chrysostomou 1991)

More complex macromodels were hence proposed, still typically based on a number of diagonal struts.

Thiruvengadam proposed the use of a multiple-strut model to simulate the effect of the infill panel. This particular model consists of a moment-resisting frame with a large number of pin-jointed diagonal and vertical struts. Initially, a perfect frame-infill bond condition is assumed, and the lateral stiffness of the infill, by its shear deformation, is modeled by a set of pin-ended diagonal struts running in both directions. These diagonals represent the shear and axial stiffness of the masonry infill. Similarly, the vertical stiffness contribution is accounted for by providing vertical struts. The objective of the aforementioned study was a realistic evaluation of the natural frequencies and modes of vibration, purposes for which the nonlinear phenomena do not play an important role. This model has been adopted by many researchers to investigate the effect of infill on the behavior of infilled frames and has been also included in FEMA-356, due to the great number of struts, as a method for modeling the special case of infilled frames with openings. Similarly, Hamburger and Chakradeo proposed a multiple-strut configuration that can account for the openings also, but the evaluation of the characteristics of the struts is rather complicated. They showed that for panels of typical configuration, the formation of these struts protects the beam-to-column connections, which have limited capacity in withstanding significant flexural demand, with plastic hinges forming instead within the mid-span region of the beam.

They postulated that this resulted in a system of significant strength, stiffness, and ductility that behaves much like the modern eccentrically braced frame systems. Such behavior could, in part, be responsible for the observed good performance of these buildings in the 1906 San Francisco earthquake (Hamburger and Meyer 2006).

The main advantage of the multiple-strut models, in spite of the increase in complexity, is the ability to represent the actions in the frame more accurately. Symmakezis and Vratsanou (1986) employed five parallel struts in each diagonal direction. It was stressed how different contact lengths play a significant effect on the bending moment distribution in the frame members.

Chrysostomou (1991, Chrysostomou et al. 2002) aimed at obtaining the response of infilled frames under earthquake loading by taking into account both stiffness and strength degradation of infills. Each infill panel was modeled by six compression-only inclined struts (Fig. 3). Three parallel struts were used in each diagonal direction and the off-diagonal ones were positioned at critical locations along the frame members. These locations are specified by a parameter α , which represents a fraction of the length or height of a panel and is associated with the position of the formation of a plastic hinge in a beam or a column. At any point during the analysis of the nonlinear response, only three of the six struts are active, and the struts are switched to the opposite direction whenever their compressive force reduced to zero.

In order to conduct nonlinear analysis, the force-displacement relationships corresponding to the equivalent strut model must be adequately defined. The modeling of hysteretic behavior increases not only the computational complexity but also the uncertainties of the problem.

In Chrysostomou's model, the hysteretic behavior of the six struts is defined by a hysteretic model, which consists of two equations. The first equation defines the strength envelope of a structural element and the second defines its hysteretic behavior. The shape of the envelope and the hysteretic loops is controlled by six parameters, all of which have physical meaning and can be obtained from experimental data. The advantage of this strut configuration over the single diagonal strut is that it allows the modeling of the interaction between the infill and the surrounding frame and it takes into account both strength and stiffness degradation of the infill, which is vital for determining the response of infilled frames subjected to earthquake load.

Saneinejad and Hobbs developed a method based on the equivalent diagonal strut approach for the analysis and design of steel or concrete frames with concrete or masonry infill walls subjected to in-plane forces. The proposed analytical model assumes that the contribution of the infill panel to the response of the infilled frame can be modeled by replacing the panel by a system of two diagonal masonry compression struts. The method takes into account the elastoplastic behavior of infilled frames considering the limited ductility of infill materials. Various governing factors such as the infill aspect ratio, the shear stresses at the infill-frame interface, and relative beam and column strengths are accounted for in this development. This model has been adopted by Madan et al. (1997) for static monotonic loading, as well as quasi-static cyclic loading. This model for masonry infill panels was implemented in IDARC 2D Version 4.0 (Vales et al. 1996), a computer-based analytical tool for the inelastic analysis and damage evaluation of buildings and their components under combined dynamic, static, and quasi-static loading.

El-Dakhkhni (2000, 2002) and El-Dakhkhni et al. (2001) suggested replacing the infill wall by

one diagonal and two off-diagonal struts, on making use of the orthotropic behavior of the masonry wall as well as on some experimental observations and analytical simplifications, in order to simplify the nonlinear modeling of these structures.

Crisafulli investigated the influence of different multiple-strut models on the structural response of infilled reinforced concrete frames, focusing on the stiffness of the structure and the actions induced in the surrounding frame. Numerical results, obtained from the single-, two-, and three-strut models, were compared with those corresponding to a refined finite element. The lateral stiffness of the structure was similar in all the cases considered, with lower values for two- and three-strut models. It must be noted that, for the multiple-strut models, the stiffness may significantly change depending on the separation between struts. The single-strut model underestimates the bending moment because the lateral forces are primarily resisted by a truss mechanism. On the other hand, the two-strut model leads to higher values than those corresponding to the finite element model. A better approximation is obtained from the three-strut model, although some differences arise at the ends of both columns. Although the single-strut model constitutes a sufficient tool for the prediction of the overall response and the triple-strut model is superior in precision, Crisafulli adopted the double-strut model approach, accurate enough and less complicated compared to the other models.

More recently, Crisafulli and Carr (2007) proposed a new macromodel in order to represent, in a rational but simple way, the effect of masonry infill panels. The model is implemented as a four-node panel element which is connected to the frame at the beam-column joints. Internally, the panel element accounts separately for the compression and shear behavior of the masonry panel using two parallel struts and a shear spring in each direction. This configuration allows an adequate consideration of the lateral stiffness of the panel and of the strength of masonry panel, particularly when a shear failure along mortar joints or diagonal tension

failure is expected. Furthermore, the model is easy to apply in the analysis of large infilled frame structures. The main limitation of the model results from its simplicity, since the panel is connected to the beam-column joints of the frame, being thus not able to properly predict the bending moment and shear forces in the surrounding frame. A detailed presentation as well as references to the work on macromodels of the various researchers mentioned above is given by Asteris et al. (2011).

Micromodeling

The ability to model accurately the behavior of a structural system, including the infilled RC frame, depends on experimental work. A review of the available published experimental data describing the effect of infill walls on the overall structural response of RC frames finds significant scatter in the obtained results, due to the large number of uncertainties involved in the various investigations carried out to date. This data can describe qualitatively the effect of infill walls, but it is not yet possible to quantify this effect experimentally. Since the formulation and validation of mathematical (numerical or analytical) models is based on available experimental data, the validity of the yield predictions of current software packages is currently questionable.

Due to the difficulties, limitations, and high costs associated with the testing of infilled RC frames, resort is frequently made to the use of nonlinear finite element analysis (NLFEA). The use of the FE method can provide a more detailed description of the effect of infill walls on the response of infilled frames. At the same time, it allows the investigation to be extended to structural forms more complex than the simple structural elements that are usually studied experimentally (i.e., scaled models of one- or two-story infilled frames with column height to beam length equal to values from 0.75 to 1.25). To qualify for accurately capturing the behavior of a concrete structure, a FEA package must predict the structural response within an error of up to 20 %. Such a package should also employ appropriate constitutive models and adopt nonlinear numerical procedures capable of

capturing the force redistribution and cracking processes of brittle materials.

To this end, constitutive relationships must be defined for the use of finite element models of infilled frames. The use of 3D solid, instead of linear, elements in constitutive models requires a considerably higher level of model sophistication. Models of concrete behavior are based either on regression analyses of experimental data (empirical models) or on continuum mechanics theories, which should also be verified against experimental data. Many such models have been proposed, but the application of FE packages in practical structural analysis has shown that the majority of constitutive relationships are case dependent, since the solutions obtained are realistic only for specific types of problems. The application of these packages to a different set of problems requires modification, sometimes significant, of the constitutive relationships. The situation is better for the reinforcement. However, complications arise with the introduction of bond-slip laws, which results in large discrepancies in predicted behavior.

Regarding the modeling of the infill panels, the great number of influencing factors, such as dimension and anisotropy of the bricks, joint width and arrangement of bed and head joints, material properties of both brick and mortar, and quality of workmanship, make the simulation of plain brick masonry extremely difficult. The level of complexity of the analytical model depends on whether masonry is considered as one-, two-, or three-phase material, where the three phases are comprised of the units, mortar, and unit-mortar interface.

Another level of complexity is added with the modeling of the infill-frame interface, which determines the boundary conditions of the infill and its interaction with the bounding frame. Springs and interface elements have been used by various researchers to represent the interaction between deformable structures such as these, where interfacial separation and sliding may arise.

Infill walls have also been represented by boundary elements. These are combined with FE, which can represent the bounding frame.

Assessment and Strengthening of Partitions in Buildings, Fig. 4 Finite element mesh for a non-integral infilled frame (Reprinted from Asteris et al. 2013 with permission from Elsevier)

This type of model reduces computational costs considerably, since the infill is represented by a single boundary element. However, the applicability of these models is limited to the elastic behavior of the infill; once cracks are initiated, boundary elements hold a disadvantage as they can be implemented only with extreme difficulty in nonlinear problems.

Mesh sensitivity poses a further challenge (Fig. 4). Very dense meshes are often thought to provide better results, but this is not always true when brittle materials are modeled. The size of the 3D brick FEs used for modeling concrete continua should be equivalent to the size of the cylinders used in testing. These are assumed to constitute a “material unit” for which average material properties are obtained. Hence, the volume of these specimens provides a general guideline for the size of the FE that should be used for the modeling of concrete structures. Furthermore, each Gauss point of a FE must correspond to a volume at least three times the size of the largest aggregate used in the concrete mix, in order to provide a realistic representation of concrete, rather than a description of its constituent materials.

Regarding the crack formation, the smeared-crack approach, rather than the discrete-crack approach, is usually adopted for the modeling of the cracking. With this approach, one may avoid

the complexities linked to remeshing, which is required by the discrete-crack approach.

The discrete element method (DEM) originated from the studies of fractured rock masses and is also used for the modeling of infill walls. Due to its capability of representing explicitly the motion of multiple, intersecting discontinuities, the DEM is particularly suitable for the analysis of discontinuity, such as masonry structures, where significant deformation occurs as relative motion between the blocks. The disadvantage of this element arises in the case of complicated deformation problems (e.g., beam-column component behavior in an infilled frame), where the number of triangular elements into which the area has to be discretized may become very large. The main difference between DEM and other continuum-based methods (e.g., FEM) is that the contact points in DEM are automatically updated and changed based on the “contact overlap” concept, leading to the detection of new contacts and complete detachment of blocks as the calculation process allows.

For the solution of the nonlinear dynamics problem, FEA packages use an iterative scheme, such as the Newton-Raphson method, and an implicit or explicit integration scheme. Some of these procedures have been adapted to take into account the brittle nature of the constitutive model of concrete with satisfactory results.

A large number of procedures/techniques have been used to apply micromodeling to infill frames, while taking into account all of the above parameters. Each of these models has its own merits and limitations, as well as level of complexity, and has been used to study different sets of parameters affecting the behavior of infilled frames.

The knowledge acquired over the years has made possible the development of commercial packages that provide a wide selection of elements, constitutive relationships, and solution schemes that researchers may use as tools for the study of such complex problems as the ones described above. Nevertheless, only recently have such packages been used for the study of infilled frames. A thorough discussion of the above concepts and models is presented by Asteris et al. (2013).

Reinforced Concrete Infills in Reinforced Concrete Frames

The construction of new walls is the most effective and economic method for retrofitting multistory reinforced concrete (RC) buildings, especially those with pilotis (soft ground story). Their structural and economic effectiveness increases when selected bays of an existing RC frame are fully infilled with integral RC walls replacing masonry ones. Such a method is appealing since the intervention is concentrated in only certain bays of the frame and reduces the disturbance to the inhabitants as compared to the case of using concrete jackets on the columns.

Most of the experimental research work performed in the last decades has focused on other frequently used types of retrofitting, in particular on fiber-reinforced polymers (FRP) and concrete jackets. Research on the use of RC infill walls has mainly targeted what is feasible: testing of one- to two-story specimens. However, data is lacking for taller full-scale specimens that reflect real-life applications, due to the practical difficulties associated with the high forces needed for the tests. Regarding code provisions, Eurocode 8 – Part 3 fully covers retrofitting with FRP or concrete jackets, while it does not address the retrofitting of RC frames with the addition of new walls created by infilling selected bays.

Experimental research on reinforced concrete frames converted into walls by infilling with RC has been carried out almost exclusively in Japan and Turkey. The experiments in Japan (Chrysostomou et al. 2013, 2014) were performed on a total of 27 1:3–1:4 scale single-story one-bay RC-infilled frames with RC infill walls with a thickness of 26–60 % (on the average 43 %) of the width of the frame members. The test results were compared in most cases with monolithically cast specimens of the same geometric characteristics (in which the frame and the infill wall were cast at the same time and integrally connected). The connection of the RC infill to the bounding frame was done by means of epoxy-grouted dowels (17 specimens) or through mechanical devices, such as shear keys and dowels without epoxy (6 specimens). In four

other test campaigns, the thickness of a preexisting thin wall was increased by 100–150 % without any direct connection of the new wall with the bounding frame. The failure mode of all specimens was in shear (including sliding at the interface). It is interesting to note that for epoxy-grouted dowels, the force resistance of the infilled frame was on average 87 % of the integral one, while for the mechanical connections it was 80 % on average. For the increased thickness of an existing thin infill wall, the force resistance was on average 92 % of the monolithic specimen, while the displacement at failure was on average 13 % smaller than for the integral specimen. For the epoxy-grouted dowels and for the mechanical connection, the ultimate deformation was on average 55 % and 115 % larger than in the integral specimen, respectively. The results show that although a deformable connection gives a somewhat reduced strength with respect to the monolithic case, the ultimate deformation of the retrofitted structure is considerably increased.

Among the specimens tested in Turkey (Chrysostomou et al. 2013, 2014), some were single-story one-bay 1:2 and 1:3 scale, with RC infill thickness 25 % and 33 % of the width of the frame members. Others were two-story one-bay scaled at 1:3, with infill wall thickness 33 % and 40 % of the width of the members of the bounding frame. The RC infill was in most cases fully connected on the perimeter with dowels, in some cases there was a gap between the infill and the columns, while in some other cases there was no connection other than simple bearing. In one case, the rebars of the infill were welded to those of the members of the frame, instead of using dowels, and monolithic specimens (not exactly similar to the infilled ones) were included for comparison purposes. Finally, there was a two-story three-bay specimen scaled at 1:3, with the middle bay infilled with a wall with 63 % thickness of the width of the frame members. The connection was made with epoxy-grouted dowels and the failure mode was predominantly flexural. In all other cases, the single-story walls failed in shear, while the two-story walls failed in a combination of flexure and shear sliding at the base.

The test specimens used in the experiments described in the previous paragraphs correspond to walls with failure modes dominated by shear, with low aspect ratios not representative of multistory slender walls. In fact, the failure mode of multistory slender walls is controlled by bending and the design is governed by the formation of a plastic hinge at the base. In such a case, shear will not have a detrimental effect on displacement and energy dissipation capacity. In addition, it has been shown numerically that higher modes may increase considerably the shear forces at the upper floors of a wall after the formation of a plastic hinge at the base. This aspect has never been studied experimentally because their height and number of stories has not been large enough to allow higher mode inelastic response. Another common element of past tests is the smaller thickness of the RC infill wall relative to the width of the frame members. As a result, the weak link of the structural system is either the infill wall in diagonal compression or its connection with the surrounding frame.

In order to start bridging the gap of knowledge regarding infilling of existing RC frames with RC walls, the effectiveness of seismic retrofitting of multistory multi-bay RC-frame buildings by converting selected bays into new walls through infilling with RC was studied experimentally at the European Laboratory for Structural Assessment (ELSA) of the Joint Research Centre in Ispra (Italy). Similar tests on scaled 0.75:1 specimens were performed at the Structures Laboratory of the University of Patras. Detailed description of the former results is presented by Chrysostomou et al. (2013, 2014) and for the latter by Fardis et al. (2013).

The test specimen in ELSA was designed based on a four-story prototype building structure consisting of four three-bay frames spaced at 6 m, with RC infilling of the exterior frames only. The specimen was designed at full scale to represent the two exterior frames of the prototype structure, spaced at 6 m and linked by a 0.15 m thick RC slab.

The dimension of the specimen in the direction of testing was 8.5 m (two exterior bays of

Assessment and Strengthening of Partitions in Buildings, Fig. 5 Elevation of the specimen in the lab with the south wall on the right of the picture (Chrysostomou et al. 2014 with kind permission from Springer Science and Business Media)

3.0 m and a central bay of 2.5 m), with an inter-story height of 3.0 m and a total height, excluding the foundation, of approximately 12.0 m. The structure was designed for gravity loads only using the code provisions of the 1970s in Cyprus.

In order to facilitate the study of the effect of as many parameters as possible, the walls in the two frames, which had a thickness of 0.25 m equal to the width of the beams and columns of the bounding frame, were reinforced with different amounts of reinforcement, with the north frame being the stronger of the two. Figure 5 depicts the south and north frames, with the south one being on the right of the picture.

The design approached used by Fardis et al. (2013) was adopted and two parameters were examined: (a) the amount of web reinforcement in the walls and (b) the connection detail between the wall and the bounding frame. Regarding the connection with the bounding

Assessment and Strengthening of Partitions in Buildings, Fig. 6 (a) Dowels and starter bars. (b) Dowels, starter bars, and web reinforcement

(Chrysostomou et al. 2014 with kind permission from Springer Science and Business Media)

frame, two distinct connection details were used. In the first detail, the web bars are connected to the surrounding frame through lap splicing with same diameter starter bars epoxy grouted into the frame members. Short dowels are then used in order to transfer the shear at the interface between the wall and the frame members (see bottom beam of Fig. 6a).

In the second detail, longer dowels were used to act both as dowels and as anchorage of the web panel to the surrounding frame (see left column and top beam of Fig. 6a); to this end, the dowels are considered as lap spliced with the nearest – smaller diameter – web bars. The complete wall reinforcement (including web, starter bars, and dowels) is shown in Fig. 5b.

Since the lapping of the column reinforcement can only take compression forces, a lap-splice failure in tension would be highly detrimental to the whole experiment. Therefore, in order to safeguard against this type of failure and allow the experiment to be performed without any premature failure, it was decided to reinforce the bounding columns of the wall at the first floor with three-sided CFRP (carbon-fiber-reinforced polymer) for a height of 0.60 m from the base of the column (Fig. 7).

The testing campaign consisted of two pseudo-dynamic tests (one at 0.10 g and the

Assessment and Strengthening of Partitions in Buildings, Fig. 7 CFRP reinforcement of the column to safeguard against lap-splice failure (Chrysostomou et al. 2014 with kind permission from Springer Science and Business Media)

other at 0.25 g) and a cyclic test. Some findings regarding the behavior of the structure are:

1. The structure managed to sustain an earthquake of 0.25 g without significant damage.
2. Some column lap splices failed with concrete spalling, but the structure continued to carry load.
3. The three-sided CFRPs protected the wall bounding columns at the first floor and prevented lap-splice failure.

4. The “weak” south frame behaved equally well as the “strong” north frame.
5. The slip displacements at the horizontal interfaces of the ground-floor walls were of the order of 0.8 mm, which is very close to the full engagement of the starter bars but not of the dowels.
6. The slip displacements between the wall and the bounding columns of the ground floor were of the order of 0.4 mm.
7. The behavior of the wall was mainly flexural; yielding took place at both the ground-floor and the first-floor walls.
8. The distribution of strains along the bounding columns of the walls shows that the ones for the ground floor are much larger than those of the first floor, while those of the second and third floors are negligible.
9. The two connection arrangements used behaved satisfactorily.
10. Higher mode effects appeared in the response of the structure.
11. Some vertical cracks appeared at the connection of the beams to both the exterior and the wall columns.
12. A horizontal crack appeared at the ground beam of the walls, which was the main cause for the loss of strength of the south frame.

It was demonstrated that this is a viable method for retrofitting and it can be used to strengthen existing ductility and strength-deficient structures. The recorded global and local behavior of the structure provides data for the development of numerical models, to facilitate the proposal of design guidelines for such a retrofitting method.

Strengthening of Partitions

In general, infill walls and in particular the masonry infill panels exhibit a small plastic region on the stress-strain curve due to significant decrease in stiffness, strength, and energy absorption capacity. In order to enhance the behavior of infill partitions and remove their inherent deficiencies, various researchers

have proposed methods for improving the performance of these elements.

One of the methods is to use shotcreting on the faces of masonry infills which can increase the stiffness and the lateral load capacity of the infilled frame and reduce the lateral drift at the ultimate load. Calvi and Bolognini (2001) have performed full-scale tests in which they have placed a 10 mm plaster on both sides of a masonry infill wall covering either reinforcement ($\varnothing 5$ mm or $\varnothing 6$ mm) or wire meshes and have studied the behavior of the strengthened infilled frame. Based on their observations from the experiments, the introduction of some reinforcement in the mortar layers, with a geometrical percentage lower than 1 %, will almost double the acceleration levels for the occupational and damage limit states.

Another technique is the use of fiber-reinforced polymer (FRP) reinforcement to enhance the overall response of such systems. Several experimental studies have been performed which demonstrate that significant improvement of strength and energy absorption capacity can be achieved if adequate anchoring is provided.

Altin et al. (2008) investigated experimentally the behavior of strengthened masonry-infilled reinforced concrete (RC) frames using diagonal carbon fiber-reinforced polymer (CFRP) strips under cyclic loads. Test results indicated that, CFRP strips significantly increased the lateral strength and stiffness of perforated clay brick-infilled nonductile RC frames. Specimens receiving symmetrical strengthening showed higher lateral strength and stiffness, compared to the ones at which CFRP strips of the same width were applied to one of the interior or exterior surface of the infill wall. In the latter case, similar lateral strength and stiffness was obtained, irrespective of the side of placement of the strips.

Lunn and Rizkalla (2009) used glass fiber-reinforced polymer (GFRP) systems for increasing the out-of-plane resistance of infill masonry walls to loading. They have concluded that GFRP strengthening of infill masonry walls is effective in increasing the out-of-plane load-carrying capacity when proper anchorage of the FRP laminate is provided. They also note that the latter has a significant effect on the failure mode of the assemblage.

Papanicolaou et al. (2007) have used the textile-reinforced mortar (TRM), which is a new structural material, for testing its capability for increasing the load-carrying capacity and deformability of unreinforced masonry walls subjected to cyclic in-plane loading. TRMs comprise fabric meshes made of long woven, knitted, or even unwoven fiber rovings in at least two directions. The density of rovings in each direction can be controlled independently, thus affecting the mechanical characteristics of the textile and the degree of penetration of the mortar matrix through the mesh openings.

Based on the experimental results, the authors stated that, in terms of strength, TRM jackets are at least 65–70 % as effective as FRP jackets with identical fiber configurations. In terms of deformability, of crucial importance in seismic retrofitting of unreinforced masonry walls, TRM jacketing for shear walls is about 15–30 % more effective than FRP. They therefore conclude that TRM jacketing is an extremely promising solution for strengthening and seismic retrofitting of unreinforced masonry walls subjected to in-plane loading.

A more recent development is the use of engineered cementitious composites (ECC) which are a special class of fiber-reinforced cement-based composite materials, typically reinforced with polyvinyl alcohol fibers. Deghani et al. (2013) have tested in diagonal compression a number of specimens with different ECC-strengthening configuration, and they evaluated their in-plane deformation and strength properties, including the post-peak softening behavior. They state that the proposed technique can effectively increase the shear capacity of masonry panels (1.5–2.8 times), improve their deformability, enhance their energy absorption capacity (35 times), and prevent the brittle failure mode.

Summary

The presence of infill walls has shown that in most cases they have beneficial effects on the behavior of structures during earthquakes and

have contributed in the prevention of collapse of many structures. It is therefore for this reason that efforts have been made to use engineered infills to retrofit existing seismic-deficient buildings, since they present an economically viable solution. Several equations have been introduced to define the stiffness of infilled frames and their capacities, which are related to a number of failure modes. These were considered in macro- and micro mathematical models that have been proposed to simulate their behavior and their interaction with the bounding frame. The former are simpler (especially the single-strut models), while the latter require a higher level of modeling sophistication. The construction of new walls is the most effective and economic method for retrofitting multistory reinforced concrete (RC) buildings, especially those with pilotis (soft story). Their structural and economic effectiveness increases when selected bays of an existing RC frame are fully infilled with integral RC walls replacing masonry ones. Recent experimental investigations make possible the quantification of this methodology and the proposal of code equations for the design of such systems. Several methods exist for improving the properties of infilled panels avoiding brittle failure and increasing their load-carrying capacity as well as their energy absorption during an earthquake.

Nonlinear static analysis; Pushover-based analysis

Introduction

Over the last few decades, it has been found that the traditional procedures, which are based on elastic linear analysis, can only approximately estimate the typically nonlinear seismic response. Therefore, the inelastic methods of analysis have been gradually introduced into practice in order to estimate the seismic response more realistically. Contrary to the elastic linear methods which can only implicitly predict the performance, the objective of the inelastic seismic analysis procedures is to directly estimate the magnitude of inelastic deformations.

In general, the most refined and accurate inelastic method is the nonlinear response history analysis (NRHA). Nevertheless, it is only sporadically used in the design practice, since it is, for the time being, still too complex for regular use. It requires substantial experience and knowledge about the modeling of the dynamic response of structures and seismic loading. Specialized software is also needed. The results are typically quite extensive, and their interpretation is often time-consuming and too demanding for an engineer with an average knowledge about seismic engineering.

To keep the inelastic analysis relatively simple and make it more apparent for practicing engineers, different static inelastic methods have been developed. Mostly they are based on the pushover analysis. They are considered more user-friendly and relatively easy to understand. They have a great advantage in specifying the seismic input, i.e., they employ the familiar elastic response spectra instead of selecting and scaling ground motion histories (Kappos et al. 2012).

From the historical point of view, pushover analysis has been typically used as a convenient tool to estimate the nonlinear properties and capacity of individual structural components or the whole structure. It typically represents the first step of different static inelastic methods. More specifically, the static nonlinear analysis is performed using the multi-degree-of-freedom (MDOF) model of the analyzed structure. The main purpose of this analysis is to define the properties of the equivalent single-degree-of-freedom (SDOF) model, which is then further

employed to estimate the maximum global displacement demand. This idea was first explored by Saiidi and Sozen (1981). Based on the estimated maximum global displacement demand, other response quantities of interest are then evaluated (see Fig. 1).

In the majority of pushover-based methods, the pushover analysis is performed in a similar manner (see section “[Pushover Analysis: Numerical Models and the Lateral Load Pattern](#)”). However, the techniques that are used to estimate the maximum displacement demand are quite different. The pushover-based methods can be classified with respect to different parameters, e.g., based on (a) the representation of the earthquake input, (b) the type of analysis performed on the SDOF model, and (c) the way how the stiffness of the equivalent SDOF model is defined.

The seismic input is represented by the acceleration response spectrum included in the codes and the displacement spectrum or with a set of accelerograms. The type of analysis is static, dynamic, or response history. The stiffness that is used to calculate the maximum displacement demand is the equivalent pre-yielding stiffness or the equivalent secant stiffness, usually obtained based on the pushover analysis. This variety of solutions can result in a different estimation of the response. In section “[Different Applications of the Inelastic Pushover-Based Analysis, Adopted in the \(Pre\)Standards and Guidelines](#),” those solutions (methods), which are adopted in Eurocode 8/3 (CEN 2005), ATC-40 (ATC 1996), and FEMA-356 (ASCE 2000), the recommended modifications in FEMA-440 (ATC FEMA 2005), and the displacement-based method, included in the NZSEE (2006), are presented. They were selected since they illustrate many of the basic concepts that are currently in use.

These methods are nowadays extensively and successfully used for the analyses of different types of buildings and bridges. Their popularity has increased since they are relatively simple to use but at the same time provide valuable information about the inelastic response, which is not possible to obtain with the elastic methods. They are a useful tool for understanding the general structural behavior corresponding to different

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 1 Version of the inelastic pushover-based analysis, included in EC8/3

seismic intensity levels. Besides other superior features, they can provide more realistic information about the force demand on brittle elements and the information on the influence of the strength degradation of individual components

on the global behavior of the structure. They can identify the critical regions in the structure. This information is particularly useful when the existing structures have been evaluated and the strengthening techniques have been selected.

However, the pushover-based analysis includes certain assumptions which limit its capabilities. Basic variants of the above code methods can be characterized as single-mode nonadaptive methods, since they assume that the response is controlled by a single predominant mode, which remains unchanged after yielding occurs. This assumption limits their application, particularly when they are used for the assessment of those existing structures which are irregular in plan and/or in elevation. Consequently, the in-plan torsion and higher modes can significantly influence their response. In such cases the extended versions of the single-mode methods are needed. As an alternative, the other types of pushover methods, accounting for the influence of higher modes (multimode methods), can be used. Some issues that influence the applicability and the way of application of the single-mode methods are briefly discussed in section “[Some Issues that Influence the Accuracy of the Inelastic \(Single-Mode\) Pushover-Based Methods.](#)” Some examples of the multimode pushover methods are briefly presented in section “[Some Alternatives to Single-Mode Pushover-Based Methods.](#)”

The assumption that the fundamental mode shape is almost invariant can also limit and complicate the application of nonadaptive methods in existing structures, where the fundamental mode can change considerably depending on the seismic intensity. This can affect the choice of the lateral load pattern in the pushover analysis and make it more complex (see section “[Different Applications of the Inelastic Pushover-Based Analysis, Adopted in the \(Pre\)Standards and Guidelines](#)”). As an alternative, adaptive pushover methods can be used. An example of these methods is briefly presented in section “[Some Alternatives to Single-Mode Pushover-Based Methods.](#)”

The methods presented in sections “[Different Applications of the Inelastic Pushover-Based Analysis, Adopted in the \(Pre\)Standards and Guidelines](#)” and “[Some Alternatives to Single-Mode Pushover-Based Methods](#)” were primarily developed for the analysis of buildings. The response of bridges, particularly in the transverse direction, can be significantly different and more

complex. Therefore, some modifications of these procedures are needed. A short overview of the application of the inelastic static methods for the analysis of bridges is presented in section “[Application of the Inelastic Static Methods to the Analysis of Bridges.](#)”

In this contribution, only those inelastic static methods that are included or referred to in the codes and national guidelines are presented. Quite a long list of other inelastic static procedures currently available in the literature can be created. Some of them are general, and some are specialized for certain types of structures. Many of them are presented in different state-of-the-art reports (e.g., FEMA 440 2005; CEB-FIB 2003; Kappos et al. 2012, etc.) or other specialized literature (e.g., Bhatt 2011).

Pushover Analysis: Numerical Models and the Lateral Load Pattern

Pushover analysis is the static nonlinear analysis which is typically performed as the first step of the majority of the inelastic static methods for the seismic assessment of the (existing) structures. The structure is subjected to the lateral load (representing the inertial forces), the intensity of which is gradually increased. The corresponding lateral displacement at a certain location (the reference point or control point) in the structure is recorded. Then the pushover curve, representing the relationship between the base shear of the structure and the registered displacements, is constructed (see Fig. 1c).

The pushover analysis is usually performed employing the MDOF model of the structure which is similar to the linear elastic finite-element models (see Fig. 1a). The most important difference is that the properties of some or all of the components of the model include the post-elastic strength and deformation characteristics in addition to the initial elastic properties. They are usually defined approximating the response observed in the experiments or the response defined by the theoretical analysis of individual components. The envelopes or backbone curves

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 2 Idealized numerical models

are approximated based on the type of the response. Typical examples are presented in Fig. 2.

Contrary to the structures designed according to modern codes, where the brittle types of failure are in general avoided, in structures which were designed before the modern principles of seismic engineering were established, different types of brittle or semi-ductile failure of their structural components may be expected. Thus for the reliable estimation of their response, the appropriate numerical models should be employed. Their properties can be defined based on different procedures, defined in the (pre)standards, guidelines, and literature (e.g., CEN 2005, FEMA-356, ATC-40, CEB-FIP 2003). It is, however, worth noting that the available models which describe quite complicated mechanisms that reduce the ductility capacity of the structural components have been less frequently investigated and are often less reliable. The properties of these models are often defined using empirical or semiempirical procedures. The results of these procedures can be considerably different.

For example, the value of the shear strength of RC components can strongly depend on the method used to estimate it. The differences between different methods depend on many parameters, e.g., the amount of the flexural and shear reinforcement, the shear span ratio, the axial force, etc. Moreover, the numerical models that can take into account the complex interaction between shear and flexural response in the nonlinear range are still under investigation and

evaluation (e.g., Mergos and Kappos 2008; Fischinger et al. 2012). Similar observations can be applied to other mechanisms, which reduce the ductility capacity of the structural components and the whole structure. Therefore, it is feasible to explore and compare different available options before the numerical model, and its properties are defined. All uncertainties related to the material properties should also be properly explored.

In the pushover analysis, the MDOF model of the structure is subjected to lateral forces that are intended to simulate the inertial forces expected in the building during an earthquake. They are usually distributed according to a selected (mostly invariant) pattern. It significantly influences the pushover curve and further determines the relative magnitudes of the shear forces, the moments, and deformations within the structure; therefore, it should be carefully selected, depending on the properties of the analyzed structure and the expected response. The distribution of the lateral inertial forces will in general vary continuously during the earthquake response, depending on the gradual formation of the plastic hinges in the structure. To take into account these changes, in many codes and guidelines, it is recommended to perform an analysis, taking into consideration at least two lateral force patterns. Typically the distribution of forces proportional to the fundamental mode of vibration in the elastic range and the uniform distribution are recommended. Then the most adverse results are taken into consideration. Other solutions

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 3 In some structures (e.g., with “soft” story), the deflection line can considerably change after yielding

recommended in the codes are presented in section “[Different Applications of the Inelastic Pushover-Based Analysis, Adopted in the \(Pre\) Standards and Guidelines](#).”

The approach described in the previous paragraph is in general appropriate for many structures, which are designed according to modern standards. However, in some older existing structures, this solution is not always suitable.

For example, in medium-rise frame buildings, which are designed according to capacity-design principles (where the columns’ flexural strength exceeds the beam flexural strength), the triangular and uniform distribution are typically applied. In existing medium-rise buildings, this is also an appropriate solution, but only if the beam-sway mechanism is the most likely to be developed. In other words, the structure does not include a so-called soft. In opposite cases, the uniform distribution may not be able to frame the range of actions that may occur during the actual dynamic response. Thus a rather complex choice of the lateral force pattern may be needed. The response of such structures in the elastic range will be approximately linear (see Fig. 3). In the nonlinear range, the displacement pattern can considerably change after the formation of the plastic hinges, as is illustrated in Fig. 3. In such cases, some (pre) standards (e.g., FEMA-356, ATC-40) recommend the use of the adaptive load pattern, which can take into account changes of the displacement response shape corresponding to the seismic intensity applied. An alternative solution is the adaptive pushover-based methods (one of which is presented in section “[Some Alternatives to Single-Mode Pushover-Based Methods](#)”). Note, however, that if either the adaptive load

pattern is used or the adaptive methods are applied, the analysis procedure is more complex and more demanding.

Similar observations to those presented above can be applied, e.g., to the RC dual and wall buildings, with the reinforcement that does not meet the requirements of current codes (e.g., where plastic hinges can form at the elevations above the foundations).

The accuracy of different lateral load patterns in structures where the higher modes have an important influence on the response is discussed in sections “[Some Issues that Influence the Accuracy of the Inelastic \(Single-Mode\) Pushover-Based Methods](#)” and “[Application of the Inelastic Static Methods to the Analysis of Bridges](#)”.

Different Applications of the Inelastic Pushover-Based Analysis, Adopted in the (Pre)Standards and Guidelines

The static pushover analysis has no rigorous theoretical foundation. It is based on the assumption that the response of the structure (MDOF system) can be estimated using the results of the analysis of an equivalent SDOF oscillator (see Fig. 1). This means that it is assumed that the response is governed by one invariant mode of vibration. In general this is incorrect. However, the assumption is approximately fulfilled in many (regular) structures, where the influence of the higher modes is negligible and the deflection shape is almost invariable. Thus the seismic response of these MDOF systems is quite accurately estimated based on the analysis of an equivalent SDOF model. It is not the intention of this article

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 4 Two different concepts, which are used to define the properties of the equivalent SDOF model

to explain the theoretical background of the formulation of the equivalent SDOF system, since it can be found elsewhere (e.g., Krawinkler and Seneviratna 1998). Here, different applications of this basic concept, which are typically used for the assessment of the existing structures, are overviewed.

In most of the modern (pre)standards and guidelines for the assessment of existing structures, the simplest form of the pushover-based analysis is included. All methods that are included in these documents are based on the same basic concept presented above. However, these methods are not the same. The procedures which are used to define the properties of the equivalent SDOF model and those which are used to define the seismic demand of this model are different. In general two different approaches are used. The properties of the equivalent SDOF system are defined either based on the equivalent pre-yielding stiffness or based on the equivalent secant stiffness (see Fig. 4a, b).

If the first approach is employed, the maximum response of the SDOF oscillator is typically defined based on the 5 % damped acceleration spectra proposed in the codes. The target displacement of the equivalent SDOF system is obtained using the equal displacement rule approximation (see Fig. 4c). Since this approximation is only suitable for the medium- and long-period

structures, the displacements are corrected for short-period structures. This approach is applied in, e.g., Eurocode 8/3 (EC8/3) and implicitly in FEMA-356 (see sections “Eurocode 8/3 (CEN 2005)” and “FEMA-356”). In FEMA-356, the maximum seismic displacements, estimated based on the analysis of SDOF system, are additionally corrected to take into account different issues which are not included in the pushover-based analysis such as strength degradation, P- Δ effect, etc.

If the secant stiffness is used to define the properties of the equivalent SDOF oscillator, typically the overdamped acceleration spectra are used (see Fig. 4d). Actually the capacity spectrum method approach is followed. It is explained later in section “ATC-40” where the method included into the ATC-40 is presented.

In the NZSEE 2006, different inelastic methods are included. The one which is conceptually different from those in other standards is described in this article (see section “FEMA-440”). Contrary to the previously mentioned procedures, the maximum seismic displacement at the reference point is assumed at the beginning of the analysis taking into account the estimated capacity of the structure. It is then used to estimate the properties of an equivalent SDOF model. The dynamic properties of the SDOF model are defined based on the secant stiffness corresponding to the assumed maximum

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 5 (a) Idealization of the capacity curve in EC8/2, (b) idealization of the pushover curve in FEMA 356

displacement. The seismic demand is estimated using the overdamped displacement spectra, derived from the 5 % damped acceleration spectra.

Since the methods included in different codes are conceptually different, they are presented in more detail in the next subsections. The FEMA-356 and ATC-40 methods were evaluated in the document FEMA-440, where their modifications are proposed. The main observations and the proposed modifications are presented in section “ATC-40.” The matters of accuracy and different issues that can influence the pushover-based analysis of buildings are discussed in section “Some Issues that Influence the Accuracy of the Inelastic (Single-Mode) Pushover-Based Methods.” The estimation of the response of bridges using the inelastic pushover-based analysis is presented in section “Application of the Inelastic Static Methods to the Analysis of Bridges.”

Eurocode 8/3 (CEN 2005)

The method that is included in Eurocode 8/3 (EC8/3) was developed by Fajfar in the 1980s. Its description can be found in (Fajfar 1999). It is included in different parts of the Eurocode 8 standards. Actually the EC8/3 refers to Eurocode 8/1 (CEN 2004) – EC8/1 – and its informative annex B, where the suggested way of application of the method is presented. It is overviewed in Fig. 1.

In the first step, the pushover curve is constructed applying forces proportional to the assumed displacement shape. In EC8/3 it is required to consider at least two force patterns: (a) *modal pattern* – proportional to the lateral forces consistent with the lateral force

distribution determined in an elastic analysis – and (b) *uniform load pattern*.

Based on the pushover analysis, the properties of the equivalent SDOF model are calculated. First, the pushover curve is converted to the capacity curve. Displacements and forces are divided by the transformation coefficient:

$$\Gamma = \frac{\sum m_i \phi_i}{\sum m_i \phi_i^2} \quad (1)$$

m_i is the mass at the location i in the structure (e.g., mass of i th floor of the building), and ϕ_i is a corresponding component of the assumed displacement shape.

Then the *equivalent pre-yielding stiffness* of the equivalent SDOF model k^* is defined as is shown in Fig. 5a. The elastic-perfectly plastic idealization is proposed.

The mass of the SDOF oscillator is determined as

$$m^* = \sum m_i \phi_i \quad (2)$$

The period of vibration of the SDOF model is defined based on the m^* and k^* :

$$T^* = 2\pi \sqrt{\frac{m^*}{k^*}} \quad (3)$$

The target displacement d_{et}^* (inelastic displacement of the equivalent SDOF oscillator) is defined as

$$d_{et}^* = S_e(T^*) \cdot \left(\frac{T^*}{2\pi} \right)^2 \quad (4)$$

$$d_t^* = d_{et}^* \quad (5)$$

for medium- and long-period structures with $T^* \geq T_c$, where T_c is the corner period between the short- and medium-period range. $S_e(T^*)$ is the elastic acceleration in the response spectrum at the period T^* .

The same relationship is used for short-period structures if their response is elastic. If the response is nonlinear, then the target displacement is defined as

$$d_t^* = \frac{d_{et}^*}{q_u} \left(1 + (q_u - 1) \frac{T_c}{T^*} \right) \geq d_{et}^* \quad (6)$$

where q_u is the ratio between the acceleration in the structure with unlimited elastic behavior $S_e(T^*)$ and in the structure with limited strength F_y^*/m^* :

$$q_u = \frac{S_e(T^*)m^*}{F_y^*} \quad (7)$$

In the next step, the seismic displacement of the structure (MDOF model) is defined multiplying the target displacement by the transformation coefficient Γ .

The static nonlinear analysis of the MDOF system is repeated up to the estimated seismic displacement in order to be able to analyze different aspects of the response (e.g., story drifts, shear forces, bending moments). The same loading pattern as in the first pushover analysis is employed.

If the target displacement d_t^* is quite different from the displacement d_m^* used to determine the idealized elastic-perfectly plastic force-displacement relationship, an iterative procedure may be applied.

FEMA-356

In the first step, the pushover analysis is performed. As in the EC8/3, at least two lateral force patterns need to be applied. Three possibilities are defined for the *first load pattern*: (a) forces proportional to the fundamental mode; (b) forces proportional to the values of

coefficient C_{vx} , defined in the standard; and (c) proportional to the story shear distribution calculated by combining the modal responses from a response spectrum analysis of the building. The use of patterns (a) and (b) is limited to structures where more than a 75 % mass participate in the fundamental mode. The pattern (c) can be used in structures where the period of the fundamental mode exceeds 1 s.

For the *second load pattern*, two options are defined: (a) uniform distributions and (b) an adaptive load distribution that changes when the new plastic hinges are formed (see the discussion in section “[Pushover Analysis: Numerical Models and the Lateral Load Pattern](#)”). Different options for the adaptive load distribution are referred to in Fajfar and Fischinger (1988), Eberhard and Sozen (1993), and Bracci et al. (1997).

The pushover curve is idealized as is shown in Fig. 5b. The idealization is bilinear. Note that only the case with a positive post-yield slope is presented in Fig. 5b. In the standard, the case with the negative post-yield slope is also considered. The effective period T_e is defined based on the pre-yielding stiffness, determined in the idealized pushover curve.

The seismic displacement (the term target displacement is used in FEMA-356, but it does not have the same meaning as in the EC8/3) is defined using the so-called coefficient method as

$$\delta_t = C_0 C_1 C_2 C_3 \cdot S_a \frac{T_e^2}{4\pi^2} g \quad (8)$$

where

T_e is the effective fundamental period

S_a response spectrum acceleration at the effective fundamental period

g gravitational acceleration

C_0 is the modification factor to relate the spectral displacement of an equivalent SDOF system to the roof displacement of the building's MDOF system. Actually it has a similar meaning as factor Γ in EC8/3

C_1 is the modification factor to relate the expected maximum inelastic displacements to the displacements calculated for the linear elastic response. The meaning is similar to the

relationship between d_t^* and d_{et}^* in EC8/3. For long- and medium-period structures, C_I is 1, and for short-period structures, it is

$$C_I = \frac{\left(1 + \frac{(R-1) \cdot T_s}{T_e}\right)}{R} \quad (9)$$

R is the ratio of elastic demand to the calculated strength capacity (a similar meaning to q_u in EC8/3).

The C_2 modification factor represents the effect of a pinched hysteretic shape, stiffness degradation, and strength deterioration on the maximum displacement response.

The C_3 modification factor represents increased displacements due to dynamic $P-\Delta$ effects.

ATC-40

While several similarities can be found between the EC8/3 and FEMA-356, the simplified nonlinear procedure in ATC-40 is rather different. It is based on the equivalent linearization. This is a version of the capacity spectrum method, which was first introduced by Freeman et al. (1975). The basic assumption is that the maximum displacement of the nonlinear SDOF system can be estimated from the maximum displacement of a linear elastic SDOF system that has the period and damping ratios that are larger than those of the initial values for the nonlinear system. The elastic SDOF system that is used to estimate the maximum inelastic displacements of the nonlinear system is usually referred to as the equivalent or the substitute system. The period and damping of the equivalent system are referred to as the equivalent period and equivalent damping ratio, respectively.

As in the previous two methods, the pushover analysis is performed first. In general, ATC-40 recommends the distribution of the lateral forces proportional to the fundamental mode pattern. In structures where the response considerably changes after yielding (e.g., in structures with soft stories – see the discussion in section “[Pushover Analysis: Numerical Models and the Lateral Load Pattern](#)”), the adaptive load pattern is required. In high-rise buildings or irregular

buildings, the influence of the higher modes should be properly taken into account. The higher mode effects may be determined by doing higher mode pushover analyses.

The application of the capacity spectrum technique means that both the structural capacity curves and the demand response spectra are plotted in the spectral acceleration versus the spectral displacement domain and compared. Therefore in the next step, the pushover curve is converted to the capacity spectrum curve using the modal shape vectors, participation factors, and modal masses obtained from a modal analysis of the structure. The capacity spectrum curve represents the relationship between accelerations S_a and displacements S_d of the equivalent SDOF oscillator. Then the standard elastic acceleration spectrum (corresponding to 5 % damping) is converted to the ADRS format, where the spectral accelerations are presented as a function of the corresponding spectral displacements (see Fig 4d). In this way, the capacity curve and the seismic demand can be plotted on the same axes and compared.

The capacity spectrum method of equivalent linearization assumes that the equivalent damping of the system is proportional to the area enclosed by the capacity curve. The equivalent period, T_{eq} , is assumed to be the secant period at which the seismic ground motion demands, reduced by the equivalent damping, intersect the capacity curve (FEMA-440). Since the equivalent period and damping are both a function of the displacement, the solution to determine the maximum inelastic displacement (i.e., performance point) is iterative.

The equivalent period T_{eq} and effective viscous damping β_{eq} (which is used to reduce the seismic demand) are defined as

$$T_{eq} = T_0 \sqrt{\frac{\mu}{1 + \alpha\mu - \alpha}} \quad (10)$$

$$\beta_{eq} = 0,05 + \kappa \frac{2 \cdot (\mu - 1) \cdot (1 - \alpha)}{\pi \cdot \mu \cdot (1 + \alpha\mu - \alpha)} \quad (11)$$

where

T_0 is the initial period of vibration of the nonlinear system, α is the post-yield stiffness

ratio, and κ is an adjustment factor to approximately account for the changes in the hysteretic behavior in reinforced concrete structures.

The adjustment factor κ depends on the hysteretic behavior of the system. Three equivalent damping levels are defined. Type A corresponds to structures with reasonably full hysteretic loops, similar to the elastic-perfectly plastic oscillator. Type C corresponds to structures with severely degraded loops, and type B denotes the hysteretic behavior between types A and C. The value of κ and the corresponding equivalent damping is the largest for systems with a hysteretic behavior of type A. Their values decrease for degrading systems B and C. The existing buildings are in general categorized as structures of type C or B, depending on the shaking duration and hysteretic behavior of the structural components.

Based on the comparison of the capacity curve and seismic demand, the target displacement is defined. This displacement is then converted to roof displacement and other aspects of the response are defined.

The ATC-40 method is also well accepted due to the clear and useful visualization of the procedure. Note, however, that the procedure, defined in EC8/3, can also be presented in a similar manner; nevertheless, it is essentially different. The capacity curve as well as the seismic demand, defined in EC8/3, can also be converted to the ADRS format, plotted on the same axes and compared, as is presented in Fajfar (1999) and illustrated in Fig. 4c.

FEMA-440

FEMA-440 is the document where the previously described procedures (FEMA-356 and ATC-40) are evaluated. Improvements of both methods are recommended. Since the document is extended with many important observations, particularly for the existing structures, only some of the conclusions related to the methods included in FEMA-356 and ATC-40 are provided in this section. Some of them are also presented in section “Some Issues that Influence the Accuracy of the Inelastic (Single-Mode) Pushover-Based Methods.”

Some Observations and Proposed Improvements of the Procedure, Included in FEMA-356

It was observed that the characteristic periods which are used to differentiate the response of short- versus medium- and long-period structures were found to be shorter than those observed from nonlinear response history analyses. This can result in an underestimation of the inelastic deformations for the periods between the characteristic period and the periods that are approximately 1.5 times the characteristic period.

The equal displacement rule approximation was found to lead to a relatively good approximation of the maximum inelastic deformations for systems with elastic-perfectly plastic behavior and periods longer than 1 s. This is not always applicable to soft soil sites and near-fault records.

The limiting values of coefficient C_1 , which defines the ratio of elastic and inelastic deformations, can lead to a large underestimation of the displacements in short-period structures. Even if this limitation was not taken into account, the magnification of inelastic displacement demands with a decreasing lateral strength for short-period structures was found to be larger than that suggested by FEMA-356. The corrections of coefficient C_1 were proposed for short-period structures.

It was observed that in many cases the cyclic degradation does not increase the maximum displacements. Thus the use of the related coefficient C_2 is recommended only for structures with significant stiffness and/or strength degradation. Coefficient C_2 is corrected.

It was found that coefficient C_3 , which is intended to represent an increase of displacements due to the dynamic P- Δ effects, cannot adequately take into account the possibility of dynamic instability. It was proposed that this coefficient be eliminated. Instead, it was proposed to use the NRHA for all structures where the strength is below the limit proposed in FEMA-440.

Some Observations and Proposed Improvements in the Procedure Included, in ATC-40

The accuracy of the estimated maximum displacement response in long-period structures depends on the hysteretic behavior type.

In structures with hysteretic behavior type A and periods longer than about 0.7 s, the ATC-40 procedure underestimates the maximum displacements. In structures with a hysteretic behavior type B and periods longer than about 0.6 s, small underestimations or overestimations of the maximum displacements were observed. This depends on the level of lateral strength and on the site class. For structures with hysteretic behavior type C, the ATC-40 procedure leads to an overestimation of the lateral displacements regardless of the period of the structure.

In short-period structures (with periods shorter than noted in the previous paragraph), a significant overestimation of the maximum displacements were observed. The overestimation increases with decreasing strength.

It was also found that the ATC-40 assumption, where it is supposed that the inelastic deformation demands of structures with hysteretic type B will be larger than those in structures with hysteretic type A, does not agree with the results of the NRHA. According to the NRHA, these deformations were approximately the same and in some cases even slightly larger in structures with hysteretic behavior type A. The provisions of ATC-40 do not address the potential dynamic instability that can arise in systems with in-cycle strength degradation and P-D effects.

The suggested improvements of the ATC-40 procedure are presented in chapter 6 of FEMA-440. They are focused on improved estimates of the equivalent period and equivalent damping. It is concluded that generally the optimal effective period is less than the secant period and the optimal effective damping is also less than that specified in ATC-40.

More details about the accuracy, advantages, and drawbacks of both methods can be found in Appendix A of FEMA-440.

NZSEE 2006

The NZSEE 2006 addresses different methods of analysis, referred to as (a) force-based method, (b) displacement-based method, (c) consolidated force-displacement-based method, and (d) method using a nonlinear pushover analysis (the

pushover analysis is performed taking into consideration the same distribution of lateral load as in FEMA-356).

Since the displacement-based method (DBM) is different from those presented in the previous sections, it is described in more detail in the next paragraphs. The basis of the method was developed by Priestley (1995) and further evaluated in, e.g., Priestley et al. (2007). The method places a direct emphasis on establishing the ultimate displacement capacity of the lateral force-resisting elements. Contrary to the methods presented in the previous sections, where the seismic displacements were calculated using acceleration spectra, in the DBM, the displacement spectra are considered.

In the first step, the flexural and shear strengths of the critical sections of the structural components, assuming that no strength degradation occurs due to the cyclic lateral loading in the post-elastic range, are estimated. In the second step, the post-elastic deformation mechanism of the structure and the probable horizontal seismic base shear capacity (V_{prob}) are determined. It is recommended that the post-elastic mechanism is defined using the (a) simple lateral mechanism analysis (presented in the guidelines), (b) inelastic response history analysis, and (c) nonlinear pushover analysis. When the nonlinear pushover analysis is used to estimate the nonlinear response, it is performed in the same manner as in FEMA-356 (the same distribution of the lateral load is taken into account).

In the third step, the plastic rotation capacities of the structural members are determined. It is then eventually corrected if the shear failure occurs before the limits to the flexural plastic rotation capacity are reached. The story inelastic drift capacity is estimated from the plastic rotation capacities.

Considering the critical storey drift and the previously defined post-elastic deformation mechanisms, the overall displacement capacity U_{sc} and the ductility capacity μ are determined at the effective height h_{eff} of the substitute structure (an equivalent SDOF model of the structure). The effective secant stiffness k_{eff} at

the maximum displacement U_{sc} is determined as $k_{eff} = V_{prob}/U_{sc}$. Then the corresponding effective period of vibration T_{eff} is calculated as

$$T_{eff} = 2\pi\sqrt{\frac{M}{k_{eff}}} \quad (12)$$

where M is the effective mass of the substitute structure (an equivalent SDOF model of the structure). Alternatively T_{eff} can be estimated directly using the Rayleigh-Ritz equation.

Based on the evaluated ductility capacity, the equivalent viscous damping ξ_{eff} of the structure is defined. It is recommended to use the method suggested in Pekcan et al. (1999). In general the equivalent viscous damping is determined in a similar manner as in ATC-40, summing the viscous and hysteretic damping.

The structural performance factor S_p is calculated according to NZS 1170.5 (2004) and taking into consideration the detailing used in the structure. It is used to reduce the seismic design actions on a structure. The displacement demand is defined using the overdamped elastic displacement spectrum. It is defined reducing the displacement spectrum $\delta(T)$, derived from the 5 % damped elastic acceleration spectrum. The displacement spectrum $\delta(T)$ is reduced using the correction factor K_ξ :

$$K_\xi = \sqrt{\frac{7}{2 + \xi}} \quad (13)$$

where $\xi = \xi_{eff}$.

Thus the spectral displacement demand of the analyzed structure at height h_{eff} is defined as

$$U_{sd} = S_p(\%NBS)_t \delta(T_{eff}) K_\xi \quad (14)$$

where $(\%NBS)_t$ is the target percentage of the new building standard. The $\%NBS$ is essentially the assessed structural performance of the building compared with the requirements for a new building.

Then the displacement capacity U_{sc} and the demand U_{sd} are compared. If $U_{sc}/U_{sd} \geq 1$, retrofit is unnecessary to achieve $(\%NBS)_t$ and vice versa.

Some Issues that Influence the Accuracy of the Inelastic (Single-Mode) Pushover-Based Methods

In this section, some issues that can influence the accuracy of the pushover-based methods are presented: the idealization of the capacity curve, the influence of the higher modes, and the influence of the in-plan torsion. In the last two subsections, the basic observations from FEMA-440 about the strength degradation and the soil structure interaction are cited.

Idealization of the Capacity Curve

In some methods presented in section “[Different Applications of the Inelastic Pushover-Based Analysis, Adopted in the \(Pre\)Standards and Guidelines](#),” the actual capacity curve is idealized either by elastic-perfectly plastic or by a bilinear relationship (see Figs. 4 and 5). This approximation is one of the key issues, since it defines the equivalent stiffness of the equivalent SDOF model. This stiffness further influences the period of the SDOF oscillator and the estimated value of the target displacement. Thus the approximation should be carefully performed.

The approximation of the capacity curve is usually performed equating the area bounded (energy) with the actual and idealized curve (see Fig. 5). At this stage, the target displacement should be assumed, because the compared areas depend on the maximum displacement. Thus if the assumed target displacement differs considerably from the value obtained at the end of the analysis of the SDOF system, iterations are strongly recommended. Otherwise the target displacement can be poorly estimated.

In structures that do not exhibit considerable strain hardening in the nonlinear range, the elastic-perfectly plastic idealization is accurate. When the strain hardening is considerable, e.g., in some types of bridges, bilinear idealization is more appropriate (see section “[Application of the Inelastic Static Methods to the Analysis of Bridges](#)” for more details).

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 6 An example of the structure, irregular in plan and elevation

The Influence of Higher Modes

It was mentioned before that the basic variants of the methods described in section “[Different Applications of the Inelastic Pushover-Based Analysis, Adopted in the \(Pre\)Standards and Guidelines](#)” can be classified as single-mode nonadaptive methods since they assume that the response is controlled by a single predominant mode which remains unchanged after yielding occurs. This assumption limits their application. For example, when they are used for the analysis of existing structures which are irregular in elevation and/or in plan (see an example in Fig. 6), certain extensions are needed in order to take into account the important influence of higher modes and the in-plan torsion. In high-rise buildings, the influence of the higher modes can be important regardless of their irregularity. In such structures, multimode pushover methods (see section “[Some Alternatives to Single-Mode Pushover-Based Methods](#)” for more details) or NRHA can be used as an alternative to single-mode pushover-based methods.

The influence of the higher modes has been the subject of different studies. The one presented in FEMA-440 outlines the most important observations. Some of them are provided in the following paragraphs.

The nonlinear static pushover procedures appeared to be reliable for the design and evaluation of low-rise buildings. In relatively tall frame buildings, where the higher-mode response is significant, interstory drifts, story

shears, and overturning moments can deviate significantly from the NRHA.

In buildings the importance of a higher-mode effect increases with the amount of inelasticity (note that in some bridges quite the opposite trend was observed – see section “[Application of the Inelastic Static Methods to the Analysis of Bridges](#)” for more details). Typical examples are, e.g., RC shear walls, where this phenomenon has been observed years ago. An explanation can be found elsewhere (e.g., Rejec et al. 2012).

Higher-mode contributions become more significant for structures with fundamental periods that fall into the constant-velocity part of the response spectrum. Forces which are developed due to the important influence of higher modes can considerably influence the failure mechanism. Thus the pushover analysis cannot always identify this mechanism.

In FEMA-440, a single first-mode distribution was found sufficient for the estimation of displacement and other quantities that were not significantly affected by higher modes. The adaptive load distribution was sometimes better and sometimes worse than the first-mode distribution. The uniform distribution is recommended in most of the codes as the second choice in order to frame the response quantities. However, in FEMA-440 it was found that it often did not fulfill this role. The uniform distribution was found to be the worst with regard to all the monitored response quantities. Thus it was not recommended as a stand-alone option.

All the codes addressed in this entry recognize that the single-mode pushover-based methods are less efficient when the higher modes are important. Thus they require these methods to be combined with the results of the linear dynamic procedures or the multimode pushover analysis is required. Specific solutions can be found in the particular standard.

The Influence of In-Plan Torsion, Two-Dimensional (2D) Versus Three-Dimensional (3D) Analysis

The in-plan torsion can importantly influence the response of the existing structures which are irregular in plan. In such structures, the 3D analysis is generally needed. The considerable influence of in-plan torsion can be expected in torsionally flexible structures, where the first mode of vibration is torsional. Substantial torsional effects can also be obtained in one direction of structures where the second mode of vibration is torsional.

It was observed that the inelastic static methods can significantly underestimate the displacements on the stiff/strong side of such buildings (see, e.g., Kreslin and Fajfar 2012). Thus the displacements on the stiff/strong side of the structure should be increased.

Most of the (pre)codes recognized this phenomenon. Thus they require an increase in the seismic displacements, defined by inelastic static methods, due to the torsional effects. All of them require a 3D analysis of the structures where the in-plan torsion is important. According to all codes, the accidental eccentricity should be taken into account in all analyses regardless of their torsional flexibility. The specific requirements related to an increase of displacements due to the torsional effects differ from standard to standard.

In general, the 3D pushover-based analysis and torsional effects are topics that require additional investigations. Thus, they are the subjects of numerous researches, reported in the literature. An overview of these researches is recently provided in Bhatt (2011).

The Strength and Stiffness Degradation

The strength degradation, including $P-\Delta$ effects, can lead to an apparent negative post-elastic

stiffness in a force-deformation relationship for a structural model using nonlinear static procedures. The performance implications depend on the type of strength degradation (cyclic or in-cycle strength degradation). For structures that are affected by component strength losses, including $P-\Delta$ effects, occurring in the same cycle as yielding (in-cycle strength degradation), the negative post-elastic slope can lead to the dynamic instability of the structural model (FEMA-440 2005). For this reason, it is suggested that the pushover-based methods are only used if the strength of the structures is above a certain prescribed limit. Otherwise the use of the NRHA is recommended.

The Soil-Structure Interaction

There is a perception among many in the practicing engineering community that short, stiff buildings do not respond to seismic shaking as adversely as might be predicted analytically. There are several reasons why short-period structures may not respond as conventional analysis procedures predict. Among these are (a) radiation and material damping in supporting soils, (b) structures with basements that experience reduced levels of shaking, (c) incoherent input to buildings with relatively large plan dimensions, and (d) inaccuracies in modeling, including dumping of masses, neglecting the foundation's flexibility, and some elements that contribute to the strength (FEMA-440 2006). In FEMA-440 procedures, it is proposed that soil-structure interaction is incorporated into the nonlinear static analyses.

Some Alternatives to Single-Mode Pushover-Based Methods

Multimode procedures are considered as an alternative approach for the analysis of structures where the single-mode methods are less accurate. There are many multimode pushover methods described in the literature. In this section, two of them are briefly presented. The multimode pushover analysis (MPA) (Chopra et al. 2004) is selected as being representative of the

nonadaptive multimode pushover-based methods, and incremental response spectrum analysis (IRSA) (Aydinoğlu 2003) is selected as the representative of the adaptive multimode pushover-based methods. Both methods were addressed in FEMA-440. The MPA was evaluated as an alternative to the single-mode pushover-based methods, and the IRSA was recognized as the potential improvement of the inelastic analysis techniques that can be used to reliably address the MDOF effects.

The MPA Method

The MPA method was developed by Chopra and Goel (e.g., Chopra and Goel 2002). The analysis is performed in a similar manner as that presented in section “Eurocode 8/3 (CEN 2005).” However, the number of the analyses depends on the number of important modes, identified in the initial – elastic – state. The pushover analysis is performed separately for each important mode. The lateral load is proportional to the shape of the vibration mode. Based on each pushover analysis, the contribution of the related mode of vibration to the seismic displacements is defined. These contributions are then combined using the appropriate combination rule (e.g., SRSS). The method supposes that the modes of vibrations are invariant. Thus it can be classified as the nonadaptive method. This limits its applicability. When considerable changes of the mode shapes can be observed in the nonlinear range (an example is described in section “Pushover Analysis: Numerical Models and the Lateral Load Pattern”), the method is in general less reliable.

It was examined in FEMA-440 as an alternative to single-mode pushover-based methods. Taking into account a study of five buildings of very different properties, it was found to be more accurate than the single-mode pushover methods, but not completely reliable. Similar observations were obtained based on other studies, e.g., studies of bridges, presented in Kappos et al. (2012).

The IRSA Method

The IRSA method was developed by Aydinoglu (2003). It is the multimode adaptive pushover

method, which means that it can take into account the influence of the higher modes as well as their changes depending on the seismic intensity. The contributions of the different modes are considered in an incremental pushover analysis.

When the structure enters the nonlinear range, its dynamic properties are changed each time a new plastic hinge is developed. In regular structures, these changes are typically quite small. In irregular structures, the mode shapes as well as their contributions to the overall response can significantly change. IRSA can take into account these changes. More importantly, IRSA is also capable of taking into account the effect of modal coupling to the formation of the plastic hinges.

Different studies (e.g., Kappos et al. 2012) have confirmed that the method is quite reliable; however, it also has certain limitations, and thus it is not universal and cannot replace the NRHA in all cases, for example, in certain types of bridges.

Application of the Inelastic Static Methods to the Analysis of Bridges

With regard to their dimensions and structural systems, and in general with regard to their seismic response, bridges are quite different from buildings. Therefore the application of different pushover-based methods, which were originally developed for buildings, is not straightforward, particularly when the bridges are analyzed in the transverse direction. For the analysis of bridges in the transverse direction, the pushover methods in general should be applied in a slightly different manner. The analysis differs mainly regarding: (1) the choice of the reference point where the displacements are registered, (2) the distribution of the lateral load, and (3) the idealization of the capacity curve. These issues are briefly presented in the following subsections. In the last subsection, the applicability of the pushover methods for the analysis of bridges is discussed.

The Reference Point

In buildings, the center of mass of the roof is typically selected as the reference point.

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 7 An example of a highly irregular bridge

In bridges, this choice is not straightforward. The specialized standards for the design of bridges often recommend the center of mass of the deformed deck as the reference point. An alternative solution could be the top of a certain column. However, in irregular bridges, both of these solutions could be inadequate.

In general, in highly irregular bridges, such as the one presented in Fig. 7, the position of the maximum displacement can considerably vary depending on the seismic intensity. In the bridge, presented in Fig. 7, the mode shapes, their importance, and the ratios are changing depending on the seismic intensity. When the response is in the elastic range, the maximum displacement is observed close to the top of the right pier. When the yielding of the central shortest pier is reached, the station of the maximum displacement is moved toward the center of the bridge (center of mass).

Three quite different pushover curves were obtained when each of the three columns was considered as the reference point (curves P1–P3 in Fig. 8a). Consequently, the dynamic properties of the equivalent SDOF model were also

different. Since the importance of the different modes is changing considerably, depending on the seismic intensity, significantly different displacements of the structure (see curves P1–P3 in Fig. 8c) were estimated based on the pushover curves, presented in Fig. 8a. One can conclude that the pushover curve, corresponding to the column, where the maximum displacements were observed, should be used in the analysis. This is true, so far as this is the station of the maximum displacement of the superstructure, too.

The station of the maximum displacement of the superstructure in a viaduct, presented in Fig. 7, considerably changes depending on the seismic intensity. Thus, the corresponding pushover curve (see curve MD in Fig. 8b) does not coincide with any of the pushover curves constructed based on the displacements monitored at the top of a particular column. The corresponding displacements of the bridge are also significantly different from those calculated using the top of the columns as the reference points (see Fig. 8c).

Since the position of the maximum displacement is variable, it coincides with the center of mass only during stronger seismic intensities. Thus, the same conclusions as those presented in previous paragraphs can be applied for the center of mass, too.

One of the possible solutions is to consider the variable reference point when constructing the pushover curve. This means that the maximum displacement is monitored, wherever it is, in its variable position, which corresponds to a certain load level. In the case presented above, this further means that in the elastic range, the reference point is above the right pier, and after yielding of the central column, it is moved toward the center of mass. The resulting pushover curve is presented by a solid line in Fig. 8b, and the displacements of the superstructure with the bold solid line in Fig. 8c.

The Distribution of the Lateral Load

The lateral load pattern, in general, can be defined following the same basic recommendations as those for buildings: (a) distribution proportional

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 8 Pushover curves and displacement envelopes, obtained in a highly irregular viaduct, based on different reference points

to the fundamental mode of the bridge in the elastic range and (b) uniform distribution. Note however that the shape of the load pattern, proportional to the fundamental mode, depends on the type of the supports above the abutments as it is presented in Figs. 9 and 10. In regular bridges, pinned at the abutments, the parabolic distribution (see Fig. 9c) is also feasible.

The Idealization of the Capacity Curve

The idealization of the capacity curve can significantly influence the stiffness of the equivalent SDOF model and the estimated value of the maximum seismic displacement. When this stiffness is not adequately estimated, the actual and estimated maximum displacement can be significantly different. In some methods, such as that included in the EC8/3, the capacity curve is approximated using the elastic perfectly plastic idealization. However, in viaducts which are pinned at the abutments, this idealization can be inappropriate, since an underestimated equivalent stiffness of the SDOF system and an

overestimated maximum displacement (see Fig. 11) can be obtained. Namely, in bridges with pinned abutments, the capacity curve can exhibit a considerable strain hardening slope, which should be properly taken into account. This is illustrated in Fig. 11.

Applicability of Pushover-Based Methods for the Analysis of Bridges

The single-mode methods can accurately predict the response of regular bridges where the influence of higher modes is not important. This is the case where the effective mass of the predominant mode exceeds 80 % of the total mass. When the methods are nonadaptive, they can be accurately used if the mode shapes do not significantly change based on the seismic intensity.

In bridges where the superstructure is considerably stiffer than the supporting elements (piers), the influence of the higher modes is in general negligible. Typical representatives are short- and medium-span bridges (e.g., the length of a bridge is less than 500 m), which are not

a proportional to the 1st mode

$\Phi_j - 1^{\text{st}} \text{ mode}$

b uniform

$\Phi_j = 1$

c parabolic

$$\Phi_j = -\frac{4}{L^2}x^2 + \frac{4}{L}x$$

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 9 Distributions of the lateral load, appropriate for bridges that are pinned at the abutments

supported by very stiff (very short) piers (e.g., in single-column piers, the height of the columns exceeds 10 m).

Considerable changes of the mode shapes can be expected (and were observed) first of all in short bridges, where the displacements of the superstructure above the abutments are not restrained. In such bridges, the predominant mode usually changes considerably, when the damage of the side columns reduces their stiffness to such an extent that the torsional stiffness of the bridge becomes lower than its translational stiffness.

The accuracy of the single-mode pushover-based methods depends on: (a) the ratio of the superstructure stiffness and the stiffness of the bents (the length of the bridge and number and the location of the short columns along the bridge); (b) the relative strength of the columns, compared to the seismic intensity; and (c) the boundary conditions at the abutments (mostly in short bridges).

When the superstructure is stiff compared to the supporting columns (piers), it has a predominant role defining the response of the bridge. In such cases, the response is typically influenced by one predominant mode. However, if the bridge is supported by short stiff columns, they govern the response and cause the

a proportional to the instant 1st mode

$\Phi_j - \text{instant } 1^{\text{st}} \text{ mode}$

b uniform

$\Phi_j = 1$

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 10 Distributions of the lateral load, appropriate for bridges with roller supports at the abutments

significant influence of the higher modes to the deflection line of the superstructure.

In many bridges, the accuracy of the single-mode methods increases with the seismic intensities (nonlinearity). Columns yield, their stiffness is reduced, and thus the superstructure has a more important role for the overall response. However, this is not the rule. In bridges where the torsional stiffness decreases when the columns yield, the single-mode methods cannot accurately predict the response at high intensity levels, due to the emphasized torsional rotations.

In bridges with roller supports above the abutments, considerable changes of mode shapes can occur, particularly when the side spans are relatively long. When they are supported by short stiff columns in the central part of the superstructure, considerable torsional effects can be obtained.

In long bridges, the influence of the higher modes in the majority of cases does not depend on the stiffness of the columns and their strength. In such bridges, the superstructure of the standard types becomes quite flexible, and consequently the higher modes become important, regardless of the stiffness and the strength of the columns.

When the response of the bridge is considerably influenced by the higher modes or the modes of vibration are changing considerably depending on the seismic intensity, the multimode pushover

Assessment of Existing Structures Using Inelastic Static Analysis, Fig. 11 Idealization of the pushover curve

methods are needed. However, note that they also have certain limitations, which depend on their basic assumptions. For example, even quite accurate methods, such as IRSA (see section “[Some Alternatives to Single-Mode Pushover Based Methods](#)”), can fail to predict the response accurately when the bridge is supported by short stiff central columns. In such cases, the NRHA is needed.

More details and recommendations about the use of the pushover-based methods for the analysis of bridges can be found in Kappos et al. (2012).

Summary

The inelastic static pushover-based methods, which are typically used for the assessment of the existing structures, are presented. Some of the basic concepts that are nowadays used are presented in the example of the four single-mode pushover-based methods included in the codes. Some parameters that influence the accuracy of these methods are presented: selection of the lateral load pattern, idealization of the capacity curve, numerical models, influence of the higher modes, and changes of the shapes of the vibration modes depending on the seismic intensity, in-plan torsion, strength degradation, and soil-structure interaction.

Two multimode pushover-based methods, which are typical examples of nonadaptive and adaptive multimode methods, are briefly overviewed. The application of the inelastic pushover-based methods to the analysis of bridges is discussed.

Introduction

Nonlinear response history analysis (NRHA) is used in both engineering industry and academia to assess the seismic performance of structures and to validate simpler analysis methods used in design or assessment. International building codes for the design of new buildings and assessment guidelines for existing buildings generally allow NRHA to be used, although the level of detail in published guidelines is mixed, and industry practice varies. In the past, NRHA was the domain of only a few specialists, but many structural analysis packages are now available to carry it out, and many engineering consultancies have the capability.

NRHA is the most general and most detailed analytic modeled approach in the earthquake engineer's toolkit, involving the numerical solution of the equation of the motion allowing for both material and geometric nonlinearity. The response of a structure to an earthquake ground motion is evaluated at small increments of time, tracking the development of plasticity in the structure as it deforms into the inelastic range. Different algorithms are available to numerically solve for forces and displacements at the current time step in terms of those at the previous time step and the applied ground acceleration over the time interval. Analysis programs commonly used in earthquake engineering use *implicit* solution algorithms, many of which are unconditionally stable (i.e., any analysis time step will lead to

a stable evaluation of response, although small time steps are still needed for accuracy), but require iteration within each time step. Some packages used more for large-deformation analysis, such as those used in the automotive industry for crash simulation, use *explicit* solution algorithms which do not require iteration, but with the trade-off of requiring a very small time step for numerical stability (depends on application, but often of the order of 10 μ s).

The most appropriate analysis methodology is very application-dependent and can evolve as a project progresses. If it is possible to demonstrate acceptable performance of a building on the basis of simple, conservative analyses, then a very detailed NRHA may require excessive engineering resource and time. On the other hand, for unusual structures or those for which initial findings are unclear, NRHA is often justified. This is especially true for the assessment of existing structures as the potential benefit of demonstrating compliance with target performance requirements (and therefore avoiding retrofit) often outweighs the engineering costs associated with advanced analysis. Existing structures are often deficient with respect to new design requirements – both qualitatively, in terms of code-required detailing, and quantitatively, in terms of seismic demand exceeding seismic resistance. This means that simplified code inputs and methods developed for code-compliant structures (such as allowable ductility levels) may not be appropriate for noncompliant structures, and more detailed analysis may be required to assess their performance.

There are many aspects of NRHA that can affect estimates of structural response, relating to appropriate numerical inputs, modeled methodologies for different materials and structural elements, and treatment of analysis outputs. On the input side, ground acceleration histories are required that are in some way consistent with the seismic hazard at the site (e.g., a code design spectrum). Different authors recommend the use of raw unscaled ground motions recorded in real earthquakes, scaled or otherwise modified real ground motions (including spectrally matched records, which are modified such that their

response spectrum matches a target spectrum), ground motions developed from physics-based simulations of fault rupture and seismic wave passage, and those generated artificially from the modification of white noise or some other mathematical approach. On the methodological side, structures can be modeled using a very detailed 3D finite element model, simplified with 2D shell elements (especially appropriate for structural walls and diaphragms) or simplified even further into 1D “stick” elements, routinely used for moment frame and braced frame structures. Nonlinear material behavior for the latter approach may be taken into account with distributed plasticity (numerical integration of the nonlinear stress–strain behavior over the length of the element) or lumped plasticity (assuming plasticity may be concentrated in a plastic hinge at the end of each member). Finally, on the output side, there are many different response quantities that can be monitored, including interstory drifts, base shear, and plastic deformations, and it is important to be able to link real descriptions of structural performance (from onset of cracking through to full structural failure) to the outputs of the analytic model. Each analyst will treat each of these aspects in different ways, potentially leading to very different estimates of seismic response of a given structure.

This entry outlines the application of NRHA to the assessment of seismic performance of existing structures, with an emphasis on those structures that do not meet prescriptive code requirements. Section “[Performance Objectives and Assessment Methodology](#)” discusses the setting of performance objectives and how these are affected by the assessment methodology adopted. Section “[Modeling Considerations](#)” covers general aspects of nonlinear dynamic analysis, including modeled considerations and interpretation of the outputs. Section “[Published Codes, Standards and Guidelines](#)” is a summary of international published guidelines on the topic, including ASCE/SEI 41-06, Eurocode 8 Part 3, the New Zealand Society for Earthquake Engineering Recommendations, and FEMA P-58. Finally, section “[Summary](#)” is a summary of the entry.

Performance Objectives and Assessment Methodology

Target seismic performance for assessment of existing structures depends on both the needs of building owners or occupants and on regulatory requirements. In many jurisdictions, seismic assessment and retrofit are carried out on a voluntary basis, and in this case, there is significant flexibility in setting performance objectives. This does not remove the responsibility of the engineer to educate the client on the seismic risk represented by different objectives. Many clients come into the assessment process with incomplete performance targets in mind, such as “to ensure life safety” or “functional performance after an earthquake,” without a full appreciation of the uncertainties in seismic hazard definitions or the costs involved in achieving different levels of performance. Indeed, even engineers often misleadingly refer to performance objectives solely in terms of structural performance and do not refer to the fairly arbitrarily defined hazard levels with which these are associated.

Performance objectives will generally be expressed in terms of a target structural performance under one or more seismic hazard levels or a time period of exposure to the hazard. Performance objectives are expressed differently depending on the analysis to be carried out. Three potential analysis types are described in FEMA P-58 (section “[FEMA P-58: Seismic Performance Assessment of Buildings](#)”):

1. *Intensity-based assessment*, in which seismic performance and losses are evaluated for seismic input defined by a given response spectrum
2. *Scenario-based assessment*, in which the seismic input is a specific earthquake scenario, such as an historical event or potential rupture of a particular fault
3. *Time-based assessment*, in which losses are integrated over the occurrence of many potential earthquakes in a fully probabilistic way to allow estimates of, e.g., annualized seismic losses.

For intensity-based assessment (which is the default option in most codes and standards for seismic assessment, including ASCE 41, EC8-3, and the NZSEE Recommendations, reviewed in Section “[Published Codes, Standards and Guidelines](#)”), one or more performance objectives will be checked, each comprising a return period at which the probabilistic seismic hazard is evaluated and the desired structural and nonstructural performance at this hazard level. In ASCE 41, for example, the “basic safety objective” (BSO) is considered to be satisfying a life safety performance level under a 475-year return period ground motion and a collapse prevention performance level under a 2,475-year return period. Nonstructural performance objectives are also given, including a life safety objective to ensure that heavy equipment or façades do not fall and endanger life or impede egress.

Performance objectives both for assessment and (if required) retrofit design for existing structures are often allowed to be less onerous than in the design of new structures. This is justified primarily on the basis of pragmatism: incorporating seismic-resistant detailing into new buildings usually comes at a relatively small premium, whereas the cost of retrofit (including both direct and indirect costs) may be prohibitive. This is especially true of historical structures, where extensive strengthening measures may not be acceptable from a cultural heritage point of view (of course, this cultural heritage is exactly what seismic strengthening is trying to preserve in the long term). Less onerous performance objectives are also sometimes justified on the basis of a lower remaining design life than the nominal value adopted for existing structures (and therefore lower exposure period to seismic hazard). The BSO in ASCE 41, for example, is considered to represent a potentially higher risk than expected for properly designed and constructed new buildings. In jurisdictions where seismic assessment and retrofit are not obligatory, building owners may decide on performance objectives for themselves, based on a cost-benefit analysis of the cost of strengthening and the risk reduction in terms of future repair costs and potential loss of life following an earthquake.

The main goal of the latest generation of performance-based earthquake engineering guidelines (such as FEMA P-58) is to develop tools to convert engineering performance objectives into metrics that are more meaningful to other stakeholders, such as building owners, building tenants, and insurance companies. Performance may be quantified in terms of direct monetary costs (for repair or replacement), human impact (chance of casualties or fatalities), and indirect costs (time to repair, reoccupy, or return to function) – snappily summarized by the 3 Ds: “dollars, deaths, and downtime.” Performance objectives expressed in this format of course place a higher burden on the analyst – particularly for areas outside the United States, where the default fragility functions given in *PACT* for various nonstructural components may not apply. The recently developed REDiTM Rating System (Resilience-based Earthquake Design Initiative; Almufti and Willford 2013) bases its platinum, gold, and silver performance resilience objectives partly on numerical estimates of post-earthquake reoccupancy and functional recovery times and provides a useful framework for discussion of enhanced performance objectives with clients and other stakeholders.

Modeling Considerations

As with any engineering or scientific numerical modeled exercise, the outputs from NRHA are only as reliable as the specific modeled techniques used and the numerical inputs. Although NRHA is perceived as giving the most accurate estimates of building seismic performance, it has the disadvantage that model checking (of both inputs and outputs) may be hampered by complexity and potentially by computational power (e.g., the time taken to envelope results of large structural analysis models over multiple ground motions can discourage the analyst from checking all response quantities thoroughly). Analysts may be overconfident of the results of NRHA and feel that detailed modeled obviates the need to apply engineering principles to the assessment of structures.

The following subsections provide a summary of some modeled decisions and interpretations that face an analyst employing NRHA on an assessment project. Many of these aspects are covered in more detail in other chapters in this entry. The discussion is divided into aspects relating to the seismic input (ground acceleration histories), structural modeled, and treatment of outputs from the analysis.

Seismic Input

From the point of view of the structure, seismic action is felt through acceleration of the ground at the base – in both horizontal and vertical directions – and therefore NRHA requires appropriate ground acceleration histories to apply. In most cases, the seismic hazard is defined in the form of a response spectrum, and therefore compatibility with a target spectrum is one of the most important considerations in definition of ground acceleration histories, but nonstationary characteristics such as duration can also be important. Results can be very sensitive to the ground motions applied, and the ground motions to be used for a given application depend not only on the seismic hazard and expected seismic shaking at the site but also on the objectives of the analysis.

For the assessment of mean (expected) response only, current codes allow as few as three ground motions to be assessed, although if fewer than seven are used, the maximum of each response quantity across all the analyses should be used. These requirements date back to the level of computing power available in the 1980s and 1990s, and nowadays, seven is generally considered to be a sensible minimum, from which the arithmetic mean response can be taken (NEHRP Consultants Joint Venture 2011). For estimates of the statistical distribution of structural response quantities, many more ground motions will be required – NEHRP Consultants Joint Venture (2011) suggests 30 records, although this depends on the variability of structural response and the ground motions affecting the site.

There is a substantial body of literature on the development of ground motions appropriate for the NRHA of structures, and no consensus has yet

been reached among researchers and codes of practice on the most appropriate methods. Categories of ground motions applied in seismic assessment are:

- Recorded by accelerometers in real earthquakes, applied to the structural model unmodified
- Recorded in real earthquakes multiplied by a linear scaling factor to achieve compatibility with the peak ground acceleration or other scalar measure of seismic intensity (e.g., spectral acceleration at the fundamental period of the structure)
- Recorded in real earthquakes modified to achieve spectrum compatibility across a range of structural periods (*spectral matching*)
- Generated from a purely mathematical algorithm, such as modified white noise
- Derived from a physics-based simulation of the seismic wave generation and propagation process.

NEHRP Consultants Joint Venture (2011) provides a discussion of the various considerations for development of ground motions for a project.

Most literature on ground motion development considers only a single component of horizontal input and does not discuss the proper treatment of horizontal variability and the application of multiple components of ground motion to a 3D analysis model. Ground motions recorded in real earthquakes are typically not axisymmetric – i.e., they do not shake each horizontal direction equally strongly. In fact, in some cases, structures with a certain period may be shaken strongly in one direction, whereas structures with a different period may be shaken more strongly in a different direction. Figure 1 shows an example of such a case, where the 1.3-s structural response is strongest at 79° from the x -axis and the 3.0-s structural response is strongest at 161°. Grant (2011) developed the software, *RspMatchBi*, to spectrally match recorded ground motions to retain the axes of strong shaking of the original motion while matching the

Assessment of Existing Structures Using Response History Analysis, Fig. 1 Response orbits (displacement of single degree of freedom oscillators) and definition of

major and minor axes of response for PEER Record 184 from Imperial Valley event; (a) 1.3-s period response and (b) 3.0-s period response (From Grant et al. 2011)

spectra of the record to target spectra. NEHRP Consultants Joint Venture (2011) provides some discussion on the application of multicomponent ground motions to a structural model.

Structural Modeling

The most appropriate type of response history analysis model (or analysis model in general) is very application specific. If a simple and conservative model is adequate to demonstrate acceptable seismic performance, then there is little benefit in introducing extra detail and complexity. In practice, modeled requirements are different for every project, and it is not possible to give a recipe that can be followed for every application. The following are some aspects of structural analysis that are important for the use of NRHA in both the assessment of existing structures and in new design.

Linear Versus Nonlinear

Although the focus of this entry is on nonlinear analysis, the extra effort involved to introduce material and geometric nonlinearity is not always justified – particularly when target performance objectives restrict the response to the elastic or near-elastic range. This also applies at a component level – for example, force-controlled (brittle) elements are usually modeled linearly, given that their nonlinear response is generally unacceptable. Of course, even if heavily nonlinear response is acceptable, if

input seismic demand is lower than the elastic response of the structure, nonlinear deformation is not expected, and a linear model would suffice. On the other hand, when a degree of nonlinearity is expected in the structure's seismic response, explicitly modeled this nonlinearity may be necessary, allowing a more accurate estimation of the overall structural response (e.g., peak displacements or storey drifts), but also a better understanding of how seismic demand is plastically redistributed among parallel load paths following first yield.

2D Versus 3D

Regular structures in plan, for which torsional response is expected to be minimal, are often analyzed with separate 2D models for each principal axis of the structure. In engineering practice (in contrast to academic research), projects on which NRHA is considered worthwhile are seldom particularly regular, although there are of course many exceptions. 3D analysis does not introduce significant complexity in pre- and post-processing when using modern analysis packages, with the exception that the ground motion input is more complicated.

Level of Detail

A given structure can be analyzed in different levels of detail: from an equivalent single degree of freedom representation through to a detailed finite element model. Often, several different

Assessment of Existing Structures Using Response History Analysis, Fig. 2 Different levels of analysis detail for modeling an unreinforced masonry house

levels of analysis will be considered for one project: for example, simplified models at an initial stage and for subsequent model checking, a main structural model (e.g., frame members modeled as 2D beam elements) for overall performance assessment, and detailed local models to calibrate aspects of the main model (e.g., modeled force transfer within a RC joint region using 3D solid elements for concrete, 2D beam elements for reinforcing bars, and bond and friction between them defined with a mathematical model).

Three different levels of detail are shown in Fig. 2, for the NRHA of an unreinforced masonry (URM) house. Figure 2a shows an equivalent frame model, in which masonry pier flexural and shear responses are modeled with nonlinear spring or link elements. For this model, the mass is lumped at an equivalent roof height, and a rigid diaphragm connects the mass to the tops of each

of the wall piers. Figure 2b shows masonry walls modeled in 2D shell elements; masonry material models may be of a smeared crack type, in which the development of cracks in the walls is modeled explicitly, or a phenomenological hysteresis model in which backbone and cyclic hysteretic rules, based on experimental behavior, are used. Finally, Fig. 2c shows a model in which individual bricks are modeled with 3D solid elements. In this case, the interaction between bricks is described with a contact surface formulation, which allows for opening and closing of cracks between the bricks and the transfer of compression and traction across the interfaces. If calibrated correctly, this model can explicitly track the development of failure mechanisms in the URM wall up until the point of collapse.

Another example of a multilevel approach, as applied to the new design of an offshore platform, may be found in Gibson et al. (2012).

Boundary Conditions and Soil–Structure Interaction (SSI)

Although structural engineers are primarily interested in the seismic response of the building itself, in many cases, this cannot be accurately predicted without taking into account the interaction between the structure, its foundation, and the soil at the site. Soil behavior is generally nonlinear, at least for the range of strains of interest for earthquake engineering applications, but is often modeled with equivalent linear stiffness and damping properties. SSI literature (e.g., NEHRP Consultants Joint Venture 2012) refers to three main effects:

1. Inertial interaction – the forces and deformations on the structure–foundation–soil interface generated by inertial forces on the structure.
2. Kinematic interaction – the stiffening effect of the building’s foundation on the soil around it and its effect on the soil vibrations.
3. Foundation deformations – foundation elements, such as piles embedded in the soil, are subjected to deformations from the building and soil and must be designed to accommodate these movements.

SSI can be taken into account in NRHA in different levels of detail: from ignoring it (simplest), adding springs at the base of the structure to represent soil and foundation flexibility, through to a direct nonlinear finite element analysis of the soil and its interaction with structural and foundation elements. The recent guide to SSI by the NEHRP Consultants Joint Venture (2012) summarizes the state of practice and requirements of design standards and codes.

Recognizing that soil properties are typically subject to more uncertainty than structural material properties, design and assessment guidelines sometimes require a bounding approach, wherein separate analyses are carried out with lower and upper bound soil properties, and the analysis results are enveloped. Due to the nature of site response and SSI, however, there is no guarantee that this will envelope the worst-case structural response. Several guidelines suggest a bounding

approach for a serviceability level earthquake ground motion, but the use of the best-estimate soil properties for the evaluation of an ultimate level seismic response.

Material and Section Properties

Material and section properties depend on the type of modeled carried out and the hysteresis models available in the analysis software used. A common requirement of the international guidelines reviewed in section “[Published Codes, Standards and Guidelines](#)” is that member strengths should be taken based on “best-estimate” properties for deformation-controlled (ductile) responses and “lower-bound” properties for force-controlled (brittle) responses. Deformation-controlled actions include structural responses that exhibit a ductile nonlinear behavior and therefore may be permitted to deform into the plastic range without (necessarily) compromising the ability of the structure to support gravity loads and seismic forces. This includes flexure in steel and RC frame elements, axial deformation in steel braces, and rocking in masonry piers. Force-controlled actions include those responses that fail in a brittle manner when their capacity is exceeded and thus should usually be prevented to ensure structural integrity. This includes shear in frame elements and masonry piers.

Stiffnesses should be based on a best estimate, as otherwise the distribution of forces in the structure could be miscalculated. Structural modeled generally requires some degree of rationalization – e.g., plastic hinges are modeled with piecewise linear hysteretic backbones like those shown in Fig. 3 (from ASCE 41) – and the most appropriate simplifications will be application-dependent. In the backbone shown, AB is the nominal elastic range, BC the plastic range (shown with a small positive stiffness due to strain hardening and spread of plasticity), and DE the residual capacity, at which a small proportion of the peak capacity at point C is still carried, prior to final failure at point E. In ASCE 41, branch CD is modeled as very steep to account for sudden loss of strength, which may not be realistic for some component

Assessment of Existing Structures Using Response History Analysis, Fig. 3 Component force–deformation backbone behavior to ASCE 41 (Adapted from ASCE 2007)

responses (ATC 2010). When modeled RC elements with the backbone shown in Fig. 3, the initial branch (AB) is taken to represent the cracked response, with the justification that the uncracked response is only attained on the first cycle (if at all). The stiffness of branch AB is then taken as an approximation of the stiffness up to a nominal first yield point. For elements expected to be pushed far into the inelastic range (beyond point B), the stiffness of AB will usually not have a large effect on the overall structural response, but for elements that are not expected to yield or maybe not even crack, using fully cracked stiffness for AB may lead to an underestimate of forces on these elements.

Assessment standards and guidelines have requirements for material testing (nondestructive or destructive) to establish material properties for NRHA. Generally, at least some destructive testing is required for NRHA to be appropriate, unless material properties are well-documented on design documentation. This follows from the “principle of consistent crudeness” (Elms 1985), according to which excessive detail is not appropriate in one aspect of a design process if significant uncertainties remain in other aspects.

Hysteretic Response of Components

As well as member strengths and backbone response, NRHA requires a model to describe response of members under cyclic loads.

For example, if the backbone response in Fig. 3 is used to represent hysteretic response of a yielding member (such as a RC or steel beam in flexure), then unloading from the backbone may be at a stiffness close to the initial elastic stiffness of the member, and cyclic response may be close to elastoplastic. If, on the other hand, the backbone represents rocking of a structural wall, then unloading may retrace the backbone back through the origin, and the response is effectively nonlinear-elastic. A generic hysteretic response, generated using the Ibarra et al. (2005) hysteresis model, is shown in Fig. 4, under both monotonic and cyclic loading.

Most structural members’ response degrades with nonlinear cyclic loading, meaning that the strength reduces for large deformations (“monotonic degradation”) and that the stiffness and strength reduce over successive cycles out to a similar level of deformation (“cyclic degradation”). Monotonic degradation is illustrated in Fig. 4 by a decreasing monotonic backbone behavior when a certain displacement is exceeded. Cyclic degradation is shown by a reduction in the force carried under successive cycles to the same displacement level.

Degradation is especially important for those members that have not been designed with seismic-resistant detailing, but even well-detailed steel and RC plastic hinges degrade at higher levels of plastic deformation. As with other aspects of modeled, the relevance of modeled this degradation for seismic assessment depends on the type of elements in the structural system and the expected level of nonlinear demand on those elements. The plastic deformation limits tabulated in ASCE 41, for example, are artificially reduced to take into account the fact that most analysts will not include degradation in their analysis models. For more details of modeled aspects of structural degradation, see ATC (2010) and Deierlein et al. (2010). These references are more useful for modeled seismically detailed structural elements; the literature on modeled degradation in seismically deficient elements (poorly detailed RC or steel elements or URM) is not developed to the same level. The analyst should ensure that the structural model

Assessment of Existing Structures Using Response History Analysis,

Fig. 4 Component force–deformation hysteretic behavior, generated using the Ibarra et al. (2005) hysteresis model

adopted is able to accurately describe available experimental data for the level of strain expected in the analysis and the cyclic conditions expected.

Modeling Deficiencies in Structural Design

NRHA is most commonly adopted for the assessment of existing structures when the structural detailing is deficient with respect to modern code requirements, and therefore adequate seismic performance cannot be demonstrated by simpler analysis methods. Typical examples of detailing deficiencies are inadequate development lengths and splice lengths for reinforcing bars, transverse reinforcement in beam–column joints and plastic hinge regions, pre-Northridge steel beam–column connections, presence of unreinforced masonry infills in frame buildings, inadequate shear strength and/or failure to satisfy a capacity design hierarchy in beams and columns, and unreinforced masonry buildings in general. Although it may be desirable to address any of these deficiencies through retrofit when they are present, there are many cases when acceptable behavior can be demonstrated. Generally, detailing deficiencies such as splice lengths and beam–column joint details are addressed by limiting both the strength and plastic deformation capacity of the affected members. For example, when reinforcing bars are anchored with inadequate development length, ASCE 41 requires that

the capacity of the bar in question is reduced by a linear ratio of the provided to required development length and also significantly reduces plastic rotation limits by up to a factor of 10.

Model Checking and Post-Processing

The amount of post-processing required for a given NRHA model is in some ways inversely related to the amount of rationalization and simplification that has gone into the modeled effort. For example, if URM walls are modeled with a discrete element approach (e.g., Fig. 2c) – wherein all bricks and their interaction are explicitly modeled – then crack widths can be evaluated explicitly, and the “no collapse” performance requirement can be checked by observation of the state of the model at the end of the analysis. In frame analyses – with 2D beam elements used for beams and columns – if monotonic and cyclic degradation are properly accounted for, collapse response can also be observed directly. More commonly, adequate performance of deformation-controlled elements is evaluated on the basis of observed peak plastic deformations (e.g., peak plastic hinge rotations in beams and columns, peak plastic axial deformation in braces, peak drifts in RC or URM walls) compared with allowable limits from published guidelines (e.g., those considered in section “Published Codes, Standards and Guidelines”)

or experiments from the literature carried out specifically for the project. Performance of force-controlled elements is evaluated on the basis of observed forces from the analysis compared with capacities evaluated according to guidelines or engineering first principles.

As noted in section “**Seismic Input**”, analyses are typically repeated for multiple earthquake ground motions, and potentially for multiple application orientations of each ground motion, to account for the fact that record-to-record uncertainty is relatively large compared to other sources of uncertainty. Appropriate processing of structural analysis results will depend on the considerations discussed in that section. When the peak response from multiple analyses is considered (say if fewer than seven ground motions are considered as input), this does not introduce significant difficulty – every analysis carried out must demonstrate acceptable response. Consideration of mean response, however, introduces several difficulties. For purely numerical quantities (e.g., plastic hinge rotation), typically codes are interpreted to refer to arithmetic mean, whereas the geometric mean would be more consistent with the common assumption of log-normally distributed structural response. For qualitative responses, such as “collapse” versus “no collapse,” or “uplift at foundation” versus “no uplift,” means cannot be evaluated. In these cases, the median is a more appropriate measure of central tendency of analysis results. Many engineers consider more than just statistics when interpreting analysis results – even if four out of seven analyses demonstrate no collapse, most engineers would be interested in assessing how collapse occurs in the other three and, if economically possible, prevent these modes of collapse from occurring. NEHRP Consultants Joint Venture (2011) provides further discussion of how analysis and performance objectives affect ground motion development and analyses carried out.

Residual deformations can be more important than peak transient deformations for evaluating performance criteria relating to post-earthquake operability or possibility of occupancy. For example, peak deformations during the

earthquake may indicate some cracking that closes up following the earthquake and does not require structural repair. Residual deformations are sensitive to backbone characteristics (such as post-yield stiffness, line BC in Fig. 3), as well as cyclic hysteretic characteristics (such as unloading stiffness and pinching). Furthermore, estimating residual deformations in NRHA can require a significantly longer analysis, allowing time after the earthquake ground motion for the structure to settle. Residual deformations are not explicitly required to be checked in most published guidelines, although approximate limits are given in ASCE 41. FEMA P-58 discussed the estimation of residual interstory drifts in an appendix. On the basis that estimation of residual response is very sensitive to modeled and ground motion characteristics, it suggests using predefined relationships between residual and peak drifts and to not attempt to evaluate them in the main NRHA model.

Nonstructural components are seldom included in a NRHA model, and therefore their assessment is carried out in the post-processing phase. Some so-called nonstructural components, such as URM infill panels in frame buildings, should be included in the structural model, when their inclusion is expected to affect structural response. Nonstructural components are typically classified as either displacement/drift-sensitive (such as partitions or façade panels) or acceleration-sensitive (such as electrical equipment), and the performance of some equipment may be rated on the basis of a limiting peak drift or acceleration level. For more important equipment, response can be evaluated with a response history analysis using floor acceleration histories recorded in the main NRHA model or a response spectrum analysis using secondary response spectra, also from the main model. Finally, statistical performance of nonstructural components is often expressed in the form of a fragility function, which gives the probability of reaching different damage levels for a given level of acceleration or drift. Fragility functions for common types of equipment and other nonstructural components (at least for US practice) are given in FEMA P-58.

Published Codes, Standards, and Guidelines

This section provides a review of available international guidelines on the seismic assessment and retrofit design of existing structures. Regulatory requirements for demonstrating seismic performance vary, but in real projects, it is helpful to demonstrate compliance with documents such as the following to establish credibility – although this should establish a minimum duty of care and should not restrict the engineer from applying state-of-the-art methods and models when they contradict the published guidelines.

ASCE/SEI 41-06: Seismic Rehabilitation of Existing Buildings

ASCE/SEI 41-06 (ASCE 2007) – herein ASCE 41 – is perhaps the most complete published guideline available for assessment and retrofit design for existing buildings, including extensive provisions on NRHA. Acceptable nonlinear seismic performance is evaluated on a component-by-component basis (e.g., plastic rotations in beam and column plastic hinges), and all structural elements must satisfy these checks for compliance. Different limits are quantified for different performance objectives: Immediate Occupancy, Life Safety, and Collapse Prevention. Overall measures of structural performance such as interstory drifts are not explicitly checked, except to evaluate possibility of impact with adjacent buildings and in checking elements that span between stories such as reinforced concrete (RC) shear walls and nonstructural components.

ASCE 41 distinguishes between deformation-controlled and force-controlled actions, as discussed in section “[Material and Section Properties](#)”. Deformation-controlled actions are modeled with their expected (mean) strength and nonlinear response quantities, while force-controlled actions are restricted to their lower-bound (mean minus one standard deviation) strength. The nonlinear response of force-controlled actions is not usually modeled, since exceeding their linear capacity would result in a sudden shedding of their load (although see

note below about the updated version ASCE 41/SEI 41-13). Some deformation-controlled actions – such as flexure in columns of moment frames – may be inhibited for new structures using capacity design procedures, but for existing structures, it would be excessively conservative to condemn a noncompliant structure if adequate seismic performance can be demonstrated.

ASCE 41 tabulates nonlinear deformation acceptance criteria for all types of structural components; in fact, these criteria are routinely applied also for the performance-based seismic design of new structures and are referred to in guidelines for analysis and design of high-rise buildings (e.g., ATC 2010). Allowable plastic deformations are tabulated in terms of relevant characteristics such as performance objective, member slenderness (for steel braces), presence of high shear and axial load and compliance of transverse reinforcement with code requirements (for concrete beams and columns), and other non-compliances with respect to modern codes. A disadvantage of this tabular format is that sometimes small changes in assumptions (e.g., a change from “noncompliant” transverse reinforcement to “compliant” transverse reinforcement) can make a large step change to the allowable deformation, whereas the real effect modeled is likely to be continuous.

Nonlinear behavior of deformation-controlled actions is modeled following the generalized force–displacement or moment–rotation backbone illustrated in Fig. 3. Parameters (deformations and forces) to describe these curves are tabulated for every component in ASCE 41. Note that ASCE 41 does not provide guidance on modeled the cyclic response of components following the backbone in Fig. 3; therefore, modeled of hysteretic phenomena such as stiffness and strength degradation and pinching is not foreseen (see section “[Hysteretic Response of Components](#)”). ATC-72-1 (ATC 2010) notes that the force–displacement backbone represents a “cyclic envelope curve” (i.e., represents cyclically degraded response) rather than the force envelope that one would get from a monotonic test on the component. Furthermore, restricting deformations of primary structural components

to within point C on Fig. 3 ensures that the region in which cyclic degradation dominates is not reached.

The next edition of ASCE 41 – ASCE/SEI 41-13 (ASCE 2014) – has just been published and expands the remit of ASCE 41 to include the multitiered seismic assessment approach previously found in ASCE/SEI 31-03 (ASCE 2003). The nonlinear response history analysis procedures have been expanded somewhat, reflecting significantly increased application of this method and the availability of research efforts such as Deierlein et al. 2010; NEHRP Consultants Joint Venture 2010, since the publication of ASCE/SEI 41-06. Nonlinear behavior of force-controlled actions is now permitted to allow explicit modeled of post-failure redistribution following brittle failure. Finally, and importantly for this entry, the unreinforced masonry (URM) wall provisions have been updated; major changes are that bed-joint sliding is now considered a deformation-controlled action, while the pier rocking mechanism is now limited to lower axial load ratios and for piers at least 6" in thickness.

Eurocode 8 Design of Structures for Earthquake Resistance Part 3: Assessment and Retrofitting of Buildings

Eurocode 8 Part 3 (CEN 2005) – herein EC8-3 – deals with both the seismic assessment and retrofitting of existing buildings. It is interesting to note that other Eurocodes do not cover non-seismic assessment of existing structures, but it was recognized by the code developers that many older structures in Europe did not take into account seismic resistance in their design (whereas presumably gravity and wind have been taken into account – at least by common design practice if not explicit calculation). In common with the other standards considered here, EC8-3 leaves the development and details of a national program for seismic risk mitigation to the member countries, including such critical aspects as what triggers the need for assessment of an existing building, timescales over which assessment and retrofitting must take place (if required), and the performance objectives

(limit states and associated return periods of seismic action) that must be satisfied, either before or after strengthening. Performance objectives considered in the standard are defined as Near Collapse, Significant Damage and Damage Limitation – inconsistently with the performance objectives in EC8-1 for new structures – but the actual objective(s) to be checked is left to the National Annex.

Similarly to ASCE 41, EC8-3 distinguishes between ductile and brittle actions. For nonlinear analyses, capacities are evaluated on the basis of deformation for ductile actions and strength for brittle ones. Column flexure is considered a ductile action, although interestingly “strong column–weak beam” behavior is enforced for steel moment frames only (not reinforced concrete).

Acceptance criteria for nonlinear actions are contained in informative Annexes A, B, and C for RC, steel, and masonry, respectively. No guidance is given for the assessment of timber structures. Generally, for elements classified as primary components of the seismic force resisting system, allowable deformations are explicitly noted as mean minus one standard deviation estimates, and for secondary components, they are the mean values.

For RC beams and columns, allowable total or plastic rotations are expressed in terms of regression relationships on experimental data, including such aspects as section depth, shear and axial force ratios, longitudinal and transverse reinforcement ratio, and material properties. Modifications are also provided for lack of compliance with modern requirements, such as lap splices in plastic hinge zones and the use of smooth reinforcing bars. Alternative expressions are also provided for curvatures rather than rotations. Annex A is also notable for a ductility-dependent shear strength calculation and specific rules for concrete, steel, and fiber-reinforced polymer (FRP) jacketing of seismically deficient elements, including estimates of the strength and deformation capacities provided by these interventions that could be used in NRHA.

Acceptability criteria for steel elements, contained in Annex B, are more comparable to the equivalents in ASCE 41. They are expressed

as multiples of the yield displacement (for braces) or yield rotation (for flexural elements), with multipliers that are in most cases identical to those in ASCE 41, assuming Immediate Occupancy, Life Safety, and Collapse Prevention performance objectives (from ASCE 41) may be mapped directly on to Damage Limitation, Significant Damage, and Near-Collapse limit states (from EC 8-3). Rotation capacities for the three limit states are also provided for retrofitted components, using interventions such as haunched connections and reduced beam section connections.

Masonry acceptance criteria (in Annex C) are quantified in terms of wall drift – in common with ASCE 41 for flexure-controlled walls, but in contrast to ASCE 41 for shear-controlled walls for which strength criteria apply. For flexure-controlled walls, drift limits are given in terms of the slenderness ratio of width to the height of the point of contraflexure, which gives limits similar to those given in ASCE 41 for fix–fix boundary conditions of wall piers but doubles the limits for cantilever walls (mapping the limit states as discussed for steel).

Stress–strain relationships for different materials are contained in each of the other material-specific Eurocodes and may be used to develop force–displacement or moment–rotation relationships for use in nonlinear analysis. However, these typically do not consider the range of strains associated with near-collapse response of structures, and therefore in-cycle degradation of strength may not be considered (see section “[Hysteretic Response of Components](#)”). Furthermore, no guidance is provided for cyclic hysteresis models for a given structural element, except a generic statement that it “should realistically reflect the energy dissipation in the element over the range of displacement amplitudes expected in the seismic design situation.”

New Zealand Society for Earthquake Engineering (NZSEE): Assessment and Improvement of the Structural Performance of Buildings in Earthquakes

The Building Act 2004 required territorial authorities (TAs) in New Zealand to adopt

a policy on “earthquake-prone buildings” (EPBs) within 18 months of the passing of the Act. The corresponding Building Regulations defines an EPB as one that will have its ultimate capacity exceeded in earthquake ground motion one-third as strong as that required for new building design. The New Zealand Society for Earthquake Engineering developed its recommendations (NZSEE 2006) (herein “the NZSEE Recommendations”) to assist TAs in developing their policies and engineers in carrying out assessments and design of seismic rehabilitation.

NRHA is allowed by the NZSEE Recommendations, although they note that NRHA should not be the sole adopted assessment procedure and should be supplemented by the results of a simplified approach. They cite such uncertainties as flexure–shear–axial force interaction, effect of axial force on column stiffness, degrading strength characteristics, and modeled of beam–column joints. Presumably, the restriction on the use of NRHA could be relaxed somewhat if more detailed analysis models are used that reduce these uncertainties. The focus of the NZSEE Recommendations is on linear analysis supplemented by an analysis of expected yielding mechanisms, and therefore the recommendations for NRHA are reasonably limited.

Nonlinear deformation limits for concrete members in the NZSEE Recommendations are evaluated in terms of yield and ultimate curvatures and an assumed nominal plastic hinge length. The yield curvature is given as a function of the yield strain in the reinforcement and the dimension of the section, and the ultimate curvature can be evaluated from a concrete strain limit, taking into account the effect of confinement and the neutral axis depth of the section at ultimate curvature. The plastic rotation capacity of steel sections is tabulated (in the New Zealand standard for design of steel structures) as a function of the section compactness and the axial load on the member. Allowable plastic hinge rotations for steel sections range from 0.5 % to 4 % for seismic load cases (higher values are given for links of eccentrically braced frames).

The NZSEE Recommendations contain useful discussion on the modeled of URM structures; they note the importance of including the distribution of mass in a masonry building and discuss the use of finite element modeled with 2D or 3D elements. However, the guidance is more targeted towards linear analysis; they recommend using a ductility factor of 1.0 and an equivalent viscous damping value of 15 % to account for energy dissipation due to cracking, sliding, and rocking, which do not seem to be appropriate for nonlinear analysis. Nevertheless, deformation limits are given as 1 % for elements failing in a rocking mode and 0.5 % for all other elements. Unique among the documents considered here, the Recommendations also give a rotation limit for spandrels of 0.5 % (based on the clear span).

FEMA P-58: Seismic Performance Assessment of Buildings

The ATC-58 and ATC-58-1 projects developed the so-called next-generation performance-based seismic design guidelines following on from “first-generation” projects such as ASCE 41. The outcome of these projects was FEMA P-58, published in 2012 (ATC 2012). This project takes one of the main original objectives of performance-based design – communicability of seismic performance to non-engineers – to the next level by providing guidance on converting results from analytic models into estimates of casualties, repair costs, and repair time. To achieve this in a meaningful way, the framework explicitly incorporates variability and uncertainty in both structural and nonstructural response. The probabilistic loss calculations are implemented in a computer program, *PACT* (Performance Assessment Calculation Tool).

FEMA P-58 considers the three basic assessment types discussed in section “[Performance Objectives and Assessment Methodology](#).” For each of these assessment types, a similar workflow is followed. Structural performance is assessed with NRHA (or other methods) and is quantified both in terms of collapse fragility (probability distribution of the ground motion level required to cause collapse) and probability

distributions of other demand parameters associated with damage to structural and nonstructural components (e.g., peak floor acceleration and peak storey drift ratio). A building performance model is developed, which takes into account all the nonstructural components in the building and relates them to specific demand parameters (e.g., partitions in a floor are related to the storey drift in that floor). Fragility functions and consequence functions are provided for typical nonstructural components present in US buildings and incorporated in the software, *PACT*. A Monte Carlo analysis is carried out to sample each of these fragility functions to assess the expected damage and losses under the design earthquake ground motion.

FEMA P-58 evaluates economic and human losses as continuous variables, rather than checking for compliance with discrete limit states (such as “Life Safety” and “Collapse Prevention” used in ASCE 41). It is left to the building owner, engineer, or future code developer to define acceptable performance for a given project. Economic losses can be compared with the costs of seismic retrofit or with other insurance or investment costs.

Downtime calculations in FEMA P-58 are limited to estimates of repair time resulting from earthquake damage, which does not account for delays for required inspections, mobilization of engineering and contractors resources, financing, permitting, and utility disruption. It also only focuses on the time to achieve full recovery of the facility, but does not consider intermediate goals such as the time to reoccupy or return to functionality, which are of more direct concern to building owners. The downtime calculation was therefore improved as part of the development of the REDiTM Rating System (Resilience-based Earthquake Design Initiative) guidelines (Almufti and Willford 2013), taking into account input from contractors, cost estimators, bankers, building department officials, and researchers. The REDiTM Rating System uses this extended FEMA P-58 loss assessment approach to demonstrate that the REDiTM resilience objectives are satisfied – primarily for new buildings, but also applicable for existing structures.

Summary

This entry has summarized the assessment of existing structures using nonlinear response history analysis. As noted in the introduction, NRHA is no longer the domain of specialist engineering consultancies, and many commonly used software packages are available to carry it out on projects.

It has been emphasized throughout this entry that the most appropriate modeled techniques and approximations to use are very application-dependent. Published guidance aimed at accurately estimating the collapse risk of well-detailed structures in highly seismic regions is not necessarily appropriate for assessing brittle URM buildings in low to moderate seismic regions. Furthermore, every client will have different requirements, and it is not always appropriate to use the most advanced analysis methods in cases where acceptable performance can be demonstrated by simpler methods or where the level of information available is limited (according to the principle of consistent crudeness). Nevertheless, this entry has attempted to summarize the different considerations that the analyst faces when setting up and interpreting his or her NRHA models for existing structures.

Several other entries in this volume consider different aspects of NRHA, and they should be consulted for more detailed guidance on each of the modeled decisions discussed in this entry.

Advanced simulation techniques; First excursion probability; Isolation systems; Rubber bearings; Stochastic excitation

Introduction

The recent improvements in isolation system products have led to the design and construction of an increasing number of seismically isolated buildings worldwide (Ceccoli et al. 1999; Chopra 2001; Kelly 1986; Zou et al. 2010). Similarly, seismic isolation has been extensively used for seismic retrofitting of existing buildings (De Luca et al. 2001; Mokha et al. 1996). In addition, base isolation concepts are utilized for the protection from shock and vibration of sensitive components of critical facilities such as hospitals, nuclear reactors, and industrial and data center facilities. One of the difficulties in the analysis and design of base-isolated systems has been the explicit consideration of the nonlinear behavior of the isolators. Another challenge has

been the efficient prediction of the dynamic response under future ground motions considering their potential variability as well as competing objectives related to the protection of the superstructure and the minimization of base displacement. The objective of this work is to characterize the performance of base-isolated systems from a reliability point of view. In particular, the case of large-scale building models is considered here. Isolation systems composed by rubber bearings are used in the present formulation. The nonlinear behavior of these devices is characterized by a biaxial hysteretic model which is calibrated with experimental data (Yamamoto et al. 2009). First excursion probabilities are used as measures of the system reliability. In this setting, reliability is quantified as the probability that the response quantities of interest (base displacement and superstructure response) will not exceed acceptable performance bounds within a particular reference period (Lutes and Sarkani 2004). Such probabilities are estimated by a stochastic simulation method (Au and Beck 2001). The variability of future excitations is addressed by adopting a probabilistic approach which belongs to the class of point-source models (Boore 2003).

The organization of this entry is as follows: Section “[Structural Model](#)” introduces the structural model for the superstructure and base platform. The characterization of the isolation system is presented in section “[Isolation Model](#).” Section “[Excitation Model](#)” deals with the

Base-Isolated Systems, Reliability-Based

Characterization of,

Fig. 1 Schematic representation of a base-isolated finite element building model

stochastic model for the excitation. The reliability assessment and the structural response of base-isolated buildings are discussed in sections “[Reliability Measures](#)” and “[System Response](#),” respectively. In section “[Application Problem](#),” the proposed characterization is illustrated by means of a based-isolated finite element building model. The entry closes with some final remarks.

Structural Model

Finite element building models with a relatively large number of degrees of freedom are considered for modeling the superstructure, i.e., the structure above the isolation system. For illustration purposes a schematic representation of a base-isolated finite element building model under ground motion is shown in Fig. 1. In general, base-isolated buildings are designed such that the superstructure remains elastic. Hence, the superstructure is modeled as a

three-dimensional linear elastic system, while the base is assumed to be rigid in plane and it is modeled using 3 degrees of freedom. Let $x_s(t)$ be the n th dimensional vector of relative displacements of the superstructure with respect to the base and M_s , C_s , K_s be the corresponding mass, damping, and stiffness matrices. Also, let $x_b(t)$ be the vector of base displacements with three components and G_s be the matrix of earthquake influence coefficients of dimension $n \times 3$, that is, the matrix that couples the excitation components of the vector $\ddot{x}_g(t)$ to the degrees of freedom of the superstructure. The equation of motion of the superstructure is expressed in the form

$$M_s \ddot{x}_s(t) + C_s \dot{x}_s(t) + K_s x_s(t) = -M_s G_s [\ddot{x}_b(t) + \ddot{x}_g(t)] \quad (1)$$

where $\ddot{x}_b(t)$ is the vector of base accelerations relative to the ground. To complete the formulation of the combined model, the equation of motion for the base platform is written as

Base-Isolated Systems, Reliability-Based

Characterization of,
Fig. 2 Schematic
representation of a rubber
bearing

B

$$\begin{aligned} & (G_s^T M_s G_s + M_b) (\ddot{x}_b(t) + \ddot{x}_g(t)) + G_s^T M_s \ddot{x}_s(t) \\ & + C_b \dot{x}_b(t) + K_b x_b(t) + f_{is}(t) = 0 \end{aligned} \quad (2)$$

where M_b is the mass matrix of the rigid base, C_b is the resultant damping matrix of viscous isolation components, K_b is the resultant stiffness

matrix of linear elastic isolation components, and $f_{is}(t)$ is the vector containing the nonlinear isolation elements forces.

Rewriting the previous equations, the combined equation of motion of the base-isolated structural system can be formulated in the form

$$\begin{aligned} & \begin{bmatrix} M_s & M_s G_s \\ G_s^T M_s & M_b + G_s^T M_s G_s \end{bmatrix} \begin{Bmatrix} \ddot{x}_s(t) \\ \ddot{x}_b(t) \end{Bmatrix} + \begin{bmatrix} C_s & O \\ O & C_b \end{bmatrix} \begin{Bmatrix} \dot{x}_s(t) \\ \dot{x}_b(t) \end{Bmatrix} + \\ & \begin{bmatrix} K_s & O \\ O & K_b \end{bmatrix} \begin{Bmatrix} x_s(t) \\ x_b(t) \end{Bmatrix} = - \begin{bmatrix} M_s G_s \\ M_b + G_s^T M_s G_s \end{bmatrix} \ddot{x}_g(t) - \begin{Bmatrix} 0 \\ f_{is}(t) \end{Bmatrix} \end{aligned} \quad (3)$$

The above formulation can be extended to other cases as well, for example, the consideration of nonlinear models for the superstructure.

Isolation Model

Rubber bearings are considered for modeling the isolation system. Such devices have been used over many years in a number of seismically isolated buildings worldwide (Kelly 1986; Su et al. 1990; Makris and Chang 1998). They require minimal initial cost and maintenance compared to other passive, semi-active, and active energy absorption devices. A rubber bearing consists of layers of rubber and steel, with the

rubber being vulcanized to the steel plates. Rubber bearing systems are able, in principle, to support the superstructure vertically, to provide the horizontal flexibility together with the restoring force, and to supply the required hysteretic damping. Figure 2 shows a schematic representation of a rubber bearing, where D_r represents the external diameter of the isolator, D_i indicates the internal diameter, and $H_r = t_r n_r$ is the total height of rubber in the device, where t_r is the layer thickness and n_r is the number of rubber layers.

An analytical model that simulates measured restoring forces under bidirectional loadings is used in the present formulation. The model is based on a series of experimental tests conducted for real-size rubber bearings (Yamamoto

Base-Isolated Systems, Reliability-Based Characterization of, Fig. 3 Schematic representation of the decomposition of the restoring force

et al. 2009; Minewaki et al. 2009). The loading tests of seven full-scale isolators were carried out using the Caltrans Seismic Response Modification Device Test Facility at the University of California, San Diego. The specimens used in the tests were made with high damping rubber compounds. In particular, horizontal bidirectional loading tests for isolators with a diameter of 0.7 m and 1.3 m were conducted. On the basis of the test results, the model assumes that the restoring force on the rubber bearing is composed of a force directed to the origin of the isolator and another force approximately opposite to the direction of the movement of the isolator. Such decomposition of the restoring force is shown schematically in Fig. 3.

According to the model, the direction of the movement of the isolator $d(t)$ is defined in terms of the components in the x and y direction of the base displacement vector $x_b(t)$ by means of the nonlinear differential equation

$$\dot{d}(t) = \frac{1}{\alpha} \|\dot{u}(t)\| \left[\hat{u}(t) - \|\dot{d}(t)\|^\beta \hat{d}(t) \right], \quad (4)$$

$$u(0) = 0, \quad d(0) = 0$$

where the components of the vector $u(t)$ correspond to the components in the x and y direction

of the base displacement vector $x_b(t)$; $\dot{u}(t)$ is the velocity vector; $\hat{u}(t)$ and $\hat{d}(t)$ are the unit directional vectors of $\dot{u}(t)$ and $\dot{d}(t)$, respectively; and $\|\cdot\|$ indicates the Euclidean norm. The parameters $\alpha = 0.2H_r$ and $\beta = 0.7$ are positive constants that relate to the yield displacement and smoothness of yielding, respectively. Once the vector $d(t)$ has been derived, the restoring force $f(t)$ on the isolator (in the x and y direction) is expressed in terms of the unit directional vector $\hat{u}(t)$ and the vector $d(t)$ as $f(t) = -\hat{u}(t)f_e(t) - d(t)f_s(t)$, where $f_e(t)$ is the nonlinear elastic component and $f_s(t)$ is the elastoplastic component. The previous decomposition of the restoring force to elastic and dissipative components simplifies the restoring force characteristics and results in a simple and accurate model. These two forces have different appearance mechanisms and different influencing factors. For example, the dependency of these forces on factors such as temperature, vertical pressure, and maximum experienced shear strain would differ. Therefore, the previous decomposition has the potential for more general modeling of other dependencies. Based on experimental results, the components of the restoring force on the rubber bearing can be approximated as

$$f_e(t) = \begin{cases} 0.35\gamma(t)A & \text{if } 0 \leq \gamma(t) \leq 1.8 \\ \left(0.35\gamma(t) + 0.2(\gamma(t) - 1.8)^2\right)A & \text{if } \gamma(t) \geq 1.8 \end{cases} \quad (5)$$

and

$$f_s(t) = \left(0.125 + 0.015\gamma(t) + 0.012\gamma(t)^3\right)A \quad (6)$$

where A is the cross-sectional area of the rubber and $\gamma(t) = \|u(t)\|/H_r$ is the average shear strain. Validation calculations have shown that the analytical model is able to accurately simulate the test results for both bidirectional and unidirectional loading. The reader is referred to Yamamoto et al. (2009) and Minewaki et al. (2009) for a detailed description of the analytical model presented in this section.

Using the previous calibration of the analytical model by means of bidirectional loading tests, the restoring forces and those calculated by the model under unidirectional loading are compared in Fig. 4 for a medium-size rubber bearing. The test results were conducted for a maximum average shear strain of 150 %.

Base-Isolated Systems, Reliability-Based Characterization of, Fig. 4 Comparison of analytical and experimental hysteresis loops for a medium-size rubber bearing. $D_r = 0.8$ m, $H_r = 0.16$ m, $D_i = 0.15$ m

It is observed that the analytical model simulates the test results very well. Additional validation calculations have shown that the analytical model is also able to accurately simulate the test results for bidirectional loadings.

Excitation Model

The uncertain earthquake excitation is modeled as a non-stationary stochastic process. In particular, a point source model characterized by the moment magnitude M and epicentral distance r is considered in this work (Boore 2003; Atkinson and Silva 2000). The time history for a specific event magnitude M and epicentral distance r is obtained by first generating a discrete white noise sequence $z^T = \langle \sqrt{2\pi/\Delta t} z_j, j = 1, \dots, n_T \rangle$, where $z_j, j = 1, \dots, n_T$, are independent, identically distributed standard Gaussian random variables, Δt is the sampling interval, and n_T is the number of time instants equal to the duration of the excitation T divided by the sampling interval. The white noise sequence is then modulated by an envelope function $h(t, M, r)$ at the discrete time instants. Discrete Fourier transform is applied to the modulated white noise sequence. The resulting spectrum is normalized by the square root of the mean square of the amplitude spectrum. Finally, the normalized spectrum is multiplied by a ground motion spectrum $S(f, M, r)$ after which discrete inverse Fourier transform is applied to transform the sequence back to the time domain to yield the desired ground acceleration time history. The envelope function is represented by

$$h(t, M, r) = a_1 \left(\frac{t}{t_n}\right)^{a_2} e^{-a_3 \left(\frac{t}{t_n}\right)} \quad (7)$$

where

$$a_1 = \left(\frac{e}{0.2}\right)^{a_2}, \quad a_2 = \frac{-0.2\ln(0.05)}{1 + 0.2(\ln(0.2) - 1)}, \quad a_3 = \frac{a_2}{0.2} \quad (8)$$

On the other hand, the total spectrum of the motion at a site $S(f, M, r)$ is expressed as the

product of the contribution from the earthquake source $E(f, M)$, path $P(f, r)$, site $G(f)$, and type of motion $I(f)$, i.e., $S(f, M, r) = E(f, M) P(f, r) G(f) I(f)$.

The source component is given by $E(f, M) = C M_0(M) S_a(f, M)$, where C is a constant, $M_0(M) = 10^{1.5M + 10.7}$ is the seismic moment, and the factor S_a is the displacement source spectrum given by

$$S_a(f, M) = \frac{1 - \varepsilon}{1 + \left(\frac{f}{f_a}\right)^2} + \frac{\varepsilon}{1 + \left(\frac{f}{f_b}\right)^2} \quad (9)$$

where the corner frequencies f_a and f_b , and the weighting parameter ε are defined, respectively, as $\log(f_a) = 2.181 - 0.496 M$, $\log(f_b) = 2.41 - 0.408 M$, and $\log(\varepsilon) = 0.605 - 0.255 M$. The constant C is given by $C = UR_\phi VF / 4\pi\rho_s\beta_s^3 R_0$, where U is a unit-dependent factor (10^{-20}), R_ϕ is the radiation pattern, V represents the partition of total shear-wave energy into horizontal components, F is the effect of the free surface amplification, ρ_s and β_s are the density and shear-wave velocity in the vicinity of the source, and R_0 is a reference distance.

The path effect $P(f, r)$ which is another component of the process that affects the spectrum of motion at a particular site is represented by functions that account for geometrical spreading and attenuation $P(f, r) = Z(R(r)) e^{-\pi f R(r)/Q(f)\beta_s}$, where $R(r)$ is the radial distance from the hypocenter to the site given by $R(r) = \sqrt{r^2 + h^2}$, where $\log(h) = 0.15 M - 0.05$. The attenuation quantity $Q(f)$ is taken as $Q(f) = 180f^{0.45}$, and the geometrical spreading function is selected as $Z(R(r)) = 1/R(r)$ if $R(r) < 70.0$ km and $Z(R(r)) = 1/70.0$ otherwise.

The modification of seismic waves by local conditions, site effect $G(f)$, is expressed by the multiplication of a diminution function $D(f)$ and an amplification function $A(f)$. The diminution function accounts for the path-independent loss of high frequency in the ground motions and can be accounted for a simple filter of the form $D(f) = e^{-0.03\pi f}$. The amplification function $A(f)$ is based on empirical curves given for

Base-Isolated Systems, Reliability-Based Characterization of, Table 1 Parameters for the stochastic ground acceleration model

Parameter	Numerical value	Parameter	Numerical value
ρ_s (gm/cc)	2.8	β_s (km/s)	3.5
V	$1/\sqrt{2}$	R_ϕ	0.55
F	2.0	R_0 (km)	1.0

generic rock sites. An average constant value equal to 2.0 is considered.

Finally, the filter that controls the type of ground motion $I(f)$ is chosen as $I(f) = (2\pi f)^2$ for ground acceleration. The particular values of the different parameters of the stochastic ground acceleration model used in this work are given in Table 1. For a detailed discussion of the point-source model, the reader is referred to Anderson and Hough (1984), Boore et al. (1997), Atkinson and Silva (2000), and Boore (2003).

The previous excitation model is complemented by considering the moment magnitude M and epicentral distance r as uncertain. The uncertainty in moment magnitude is modeled by the Gutenberg-Richter relationship truncated on the interval $[6.0, 8.0]$, which leads to the probability density function $p(M) = b e^{-bM} / (e^{-6.0b} - e^{-8.0b})$ where $b = 1.8$ is a seismicity factor (Kramer 2003). For the uncertainty in the epicentral distance r , a lognormal distribution with mean value of 20 km and coefficient of variation equal to 35 % is considered. For illustration purposes Fig. 5 shows a typical envelope function, a ground motion spectrum, and a corresponding sample of ground motion.

Reliability Measures

The performance of base-isolated structural systems is characterized by means of a set of response functions $h_i(t, y, \theta)$, $i \in I_h$, $t \in [0, T]$, where y is the vector of controllable system parameters; θ is the vector of uncertain variables that characterizes the stochastic excitation model, i.e., the white noise sequence z and the

Base-Isolated Systems, Reliability-Based Characterization of, Fig. 5 Envelope function, ground motion spectrum, and a sample ground motion

seismological parameters M and r ; and I_h is a set of indices. The controllable system parameters are taken as the external diameter and the total height of rubber of the isolators, that is, $y^T = \langle D_r, H_r \rangle$. The probability that performance conditions are satisfied within a particular reference period T is used as a reliability measure. In this context a failure event F is defined in terms of a performance function $g(y, \theta)$ as $F(y, \theta) = g(y, \theta) \leq 0$, where

$$g(y, \theta) = 1 - \max_{i \in I_h} \left(\max_{t \in [0, T]} \frac{|h_i(t, y, \theta)|}{h_i^*} \right) \quad (10)$$

and h_i^* , $i \in I_h$ are the corresponding acceptable response levels. In particular, the probability of failure events associated with the base drift and superstructure absolute acceleration are considered in the present formulation. The probability of failure $P_F(y)$ evaluated at some particular value of the isolation system parameters y can be expressed in terms of the probability integral

$$P_F(y) = \int_{g(y, \theta) \leq 0} p(\theta) d(\theta) \quad (11)$$

where $p(\theta)$ is the multidimensional probability density function that characterizes the parameters involved in the excitation model. For systems under stochastic excitation, the probability integral involves in general a large number of uncertain parameters. Thus, the reliability estimation constitutes a high-dimensional problem. This problem is solved by applying an advanced simulation technique called subset simulation (Au and Beck 2001). In the approach, the failure probabilities are expressed as a product of conditional probabilities of some chosen intermediate failure events, the evaluation of which only requires simulation of more frequent events. Therefore, a rare event simulation problem is converted into a sequence of more frequent event simulation problems. Validation calculations have shown that subset simulation can be applied efficiently to first excursion response problems for a wide range of dynamical systems.

Details of this simulation procedure from the theoretical and numerical viewpoint can be found in Au and Beck (2001), Ching et al. (2005), and Zuev et al. (2011).

System Response

The response of base-isolated structural systems is obtained from the solution of the equation of motion that characterizes the combined system, that is, isolation system and superstructure (Eq. 3). The solution of this equation is obtained in an iterative manner due to the nonlinearity of the isolators forces. The solution scheme is implemented as follows:

- (i) At the beginning of the iteration ($l = 0$) within the time interval $[t, t + \Delta t]$, it is assumed that $\mathbf{d}_j^{(l)}(t + \Delta t) = \mathbf{d}_j(t)$ and $\mathbf{u}_j^{(l)}(t + \Delta t) = \mathbf{u}_j(t)$, $j = 1, \dots, n_I$ where $\mathbf{d}_j(t)$ and $\mathbf{u}_j(t)$ represent the direction of the movement and displacement vector of isolator number j , respectively, and n_I is the total number of isolators in the isolation system.
- (ii) The previous information and the characterization of the restoring force given in section “Isolation Model,” allow the characterization of the vector containing all nonlinear isolators forces $\mathbf{f}_{is}^{(l)}(t + \Delta t)$ (in the right-hand side of Eq. 3) is obtained.
- (iii) The solution of Eq. 3 is obtained by any suitable step-by-step integration scheme. Such solution gives the base responses $\mathbf{x}_b^{(l+1)}(t + \Delta t)$ and $\dot{\mathbf{x}}_b^{(l+1)}(t + \Delta t)$. From these quantities the isolator displacement and velocity vectors $\mathbf{u}_j^{(l+1)}(t + \Delta t)$ and $\dot{\mathbf{u}}_j^{(l+1)}(t + \Delta t)$, $j = 1, \dots, n_I$, respectively, are computed.
- (iv) The nonlinear differential Eq. 4 is integrated to obtain a new estimate for $\mathbf{d}_j(t + \Delta t)$, $j = 1, \dots, n_I$, i.e., $\mathbf{d}_j^{(l+1)}(t + \Delta t)$, and the nonlinear forces in the isolation system $\mathbf{f}_{is}(t + \Delta t)$ (in the right-hand side in Eq. 3). The solution of the equation for the evolution of the set of variables $\mathbf{d}_j(t)$, $j = 1, \dots, n_I$ is obtained by

a proper integration scheme such as the Crank-Nicolson method (Burden and Faires 2011).

- (v) The iteration starting with solving Eq. 3 needs to be repeated until the variation of the quantities $\mathbf{d}_j(t + \Delta t)$, $j = 1, \dots, n_I$ is sufficiently small between two consecutive iterations (Jensen and Sepulveda 2011).

Application Problem

The objective of the application problem is to evaluate the effect of basic design isolator characteristics such as the rubber diameter (D_r) and the height of rubber (H_r) on the reliability of a base-isolated structural system. To this end, a three-dimensional reinforced concrete building model with more than 7000 degrees of freedom is considered for the analysis. The isometric view of the finite element model is shown in Fig. 6. Material properties of the reinforced concrete structure have been assumed as follows: Young's modulus $E = 2.5 \times 10^{10}$ N/m²; and Poisson ratio $\nu = 0.2$. The total mass of the first and second floor is 7.0×10^5 kg and 6.0×10^5 kg, respectively. On the other hand, the total mass of the platform is equal to 6.0×10^5 kg. The height of each floor is 3.5 m, and the floors are modeled with shell elements with a thickness of 0.25 m. Additionally, beam and column elements are used in the model. A 5 % of critical damping is added to the structural system. For anti-seismic design purposes, the structure is equipped with a total number of 20 rubber bearings in its isolation system. The structural system is excited by a ground acceleration in the x direction and modeled as described in section “Excitation Model.” The sampling interval and the duration of the excitation are taken equal to $\Delta t = 0.01$ s and $T = 30$ s, respectively. Thus, the generation of synthetic ground motions involved more than 3000 random variables in this case. The reliability of the base-isolated system is evaluated in terms of the probability of failure events associated with the base drift and superstructure absolute acceleration. The failure event related to the base drift is defined as

Base-Isolated Systems, Reliability-Based

Characterization of,
Fig. 6 Building model
with base isolation system

B

Base-Isolated Systems, Reliability-Based Characterization of, Fig. 7 Probability of the failure event related to the base drift as a function of the isolation system parameters

$$F_{\text{drift}}(y, \theta) = 1 - \max_{t \in [0, T]} \frac{|x_{bx}(t, y, \theta)|}{x_{bx}^*} \quad (12)$$

where $x_{bx}(t, y, \theta)$ represents the base displacement in the x direction, x_{bx}^* is the critical threshold level equal to 0.25 m, and $\theta^T = \langle z_1, z_2, \dots, z_{3001}, M, r \rangle$ is the vector of random variables that characterizes the excitation.

On the other hand, the failure event associated with the superstructure absolute acceleration is given by

$$F_{\text{acceleration}}(y, \theta) = 1 - \max_{i \in I} \left(\max_{t \in [0, T]} \frac{|\ddot{x}_{sxi}^{(\text{absolute})}(t, y, \theta)|}{\ddot{x}^*} \right) \quad (13)$$

where $\ddot{x}_{sxi}^{(\text{absolute})}(t, y, \theta), i \in I$ represent the absolute acceleration of the degrees of freedom of the superstructure in the x direction and $\ddot{x}^*$ is the acceptable level of response equal to 3.94 m/s^2 .

Figure 7 shows the probability of failure in terms of the base drift response as a function of the isolation system parameters. In this figure the nominal values of the isolation parameters are set equal to $D_r = 0.75 \text{ m}$, $H_r = 0.168 \text{ m}$, and $D_i = 0.10 \text{ m}$. It is seen that there is a decrease in the probability of failure as the rubber diameter is increased. This is reasonable since the base isolation system becomes stiffer in this case. On the other hand, the probability of failure increases as the height of the rubber

Base-Isolated Systems, Reliability-Based Characterization of, Fig. 8 Probability of the failure event related to the superstructure absolute acceleration as a function of the isolation system parameters

increases. In this case the isolation system becomes more flexible.

The effects of the isolation system parameters on the superstructure absolute acceleration are shown in Fig. 8. In this figure the probability of failure in terms of the absolute acceleration of the superstructure is presented. The probability of failure increases as the rubber diameter increases. In contrast, as the height of the rubber increases, the probability of failure is decreased. Clearly these effects are opposite to the effects of the isolation system parameters on the base response. For example, the introduction of additional stiffness in the isolation system makes the structural response ineffective. In other words, this additional stiffness which controls the base displacement makes the superstructure more vulnerable. This in turn affects the primary objective of the isolation system, namely, the reduction of the superstructure response. The previous results and observations show that the protection of the superstructure and the control of the base displacement are conflicting objectives.

Summary

A reliability-based characterization of base-isolated systems under stochastic excitation has been proposed. The characterization allows to evaluate the effect of important design isolator

characteristics on the reliability of such systems. The results of the example problem indicate that the minimization of the superstructure absolute acceleration and the minimization of the base displacement are conflicting goals. For example, the provision of additional stiffness to the isolation system decreases the superstructure reliability. Contrarily, the flexibility of the isolators has a positive impact on the reliability of the superstructure. However, this flexibility may induce undesirable effects on the base isolation system. Therefore, the performance of the superstructure as well as the response of the base isolation system should be considered simultaneously for a proper characterization of base-isolated systems. It is noted that additional considerations such as the evaluation of the superstructure reliability in terms of interstory drifts can also be taken into account. This could lead to important results and conclusions. Similarly, the explicit consideration of near-field ground motions may have important implications for flexible structures such as base-isolated systems. For these systems near-field ground motions may lead to excessive base deformations and superstructure deformations with important implications for the reliability of the combined structural system (isolation system and superstructure). In summary, the proposed reliability-based characterization of base-isolated systems under stochastic excitation provides a valuable basic tool for the analyst and designer.

Bayesian Operational Modal Analysis

Siu-Kui Au

Ambient modal identification; Bayes' theorem; Modal identification; Operational modal analysis; Signal-to-noise ratio; System identification; Uncertainty law

Introduction

Operational modal analysis, or ambient modal identification, aims at identifying the modal properties (natural frequency, damping ratio, mode shape, etc.) of an instrumented structure using only the (output) vibration response (acceleration, velocity, etc.). The input excitation to the structure is not measured but is assumed to be broadband random, often referred to as “ambient.” This allows vibration data to be collected when the structure is in its working or “operating” condition without much intervention, therefore implying significant economy over free-vibration (initially excited but no input afterwards) or forced-vibration tests (known input). The broadband random assumption essentially requires that the spectral characteristics (shape) of the measured response reflect the properties of the modes rather than those of the excitation, which is assumed to be constant in the vicinity of the natural frequencies.

In the absence of input loading, the uncertainties associated with the identified modal properties are often significantly higher than those identified from free-vibration tests or forced-vibration tests. The situation is aggravated by the presence of “modeling errors” that can be significant in field tests, i.e., the structure may not obey the modeling assumptions used in identifying the modal properties.

A Bayesian system identification approach provides a fundamental mathematical framework for quantifying the uncertainties and their effects on the identification results. This article describes the basics of Bayesian operational modal analysis, covering issues on formulation, efficient computations, interpretation of results, the quantification of identification uncertainties, and their management.

The methods presented in this article make use of the FFT (Fast Fourier transform) of measured acceleration data on a selected frequency band around the modes of interest. The modes are assumed to be classically damped.

In theory, ambient modal identification can be performed in either the time domain or the frequency domain. In practice, however, a frequency domain approach is preferable because it allows a natural partitioning of information in the data for identifying the modes of interest. It significantly simplifies the identification model because it only needs to model the modes in the selected band. For well-separated modes, one can select the band to cover one mode only, so that it can be identified independently of other modes. In general, the number of modes in the identification model only needs to be equal to the number of closely spaced modes, which rarely exceeds three. In the Bayesian formulation, this does not require any band-pass filtering because it can be done by simply omitting the FFT data of the excluded bands from the likelihood function.

Using only the FFT data within a selected band also significantly reduces modeling error risk because the identification results are invariant to complexities in the excluded bands containing other modes not of interest or even dynamics that are difficult to model. The mechanical response, excitation, and channel noise are assumed to have a flat spectrum within the selected frequency band only, rather than over the whole sampling band from zero to the Nyquist frequency (half of the sampling frequency). The latter is inevitable in time-domain identification approaches.

As a literature note, operational modal analysis was first formulated using a Bayesian approach in the Master's Thesis of Yuen (1999).

This led to the time-domain formulation in Yuen and Katafygiotis (2001a), a spectral density formulation in Yuen and Katafygiotis (2001b) and later an FFT formulation in Yuen and Katafygiotis (2003). As mentioned before, the time-domain formulation is not preferred for its assumption on the prediction error and modal force. The spectral density formulation involves statistical averaging and may not make full use of the information contained in the data. The Bayesian formulation based on FFT is therefore the preferred choice. The above formulations are only computationally feasible for a small number of measured degrees of freedom (dofs). This partly explains why the formulations did not flourish and there were no applications for a number of years after the formulations first appeared. Based on the FFT formulation, fast but equivalent formulations that allow mathematical analysis and feasible implementation in general were developed in Au (2011) (see also Zhang and Au 2013) for well-separated modes, Au (2011, 2012a) for multiple (possibly close) modes, and Au and Zhang (2012a) and Zhang et al. (2015) for well-separated modes but multiple setups. Application to field or experimental data can be found in Au et al. (2012a, b), Au and To (2012), Au and Zhang (2012b), and Fan et al. (2012). See also Yuen and Kuok (2010a, b) for application of the Bayesian spectral density approach. Asymptotic uncertainty laws that provide insights on the achievable limits operational modal analysis have been developed in Au (2014a, b). Recent overviews can be found in Yuen and Kuok (2011) and Au et al. (2013).

Context

The primary objective of ambient modal identification is to identify the natural frequencies, damping ratios, and mode shapes of a constructed structure using (output) vibration response measurement at a number of measured degrees of freedom (dofs) under “ambient conditions.” The latter is a notion relative to the mode of interest. It refers specifically to the situation

where it is justified to assume that the modal (not physical) force has a constant power spectral density in the vicinity of the resonance band dominated by the mode.

Following a Bayesian approach in the frequency domain, use is made of the (scaled) FFT of the measured acceleration response at a number of dofs on the structure, denoted by $\{\hat{\mathbf{x}}_j \in R^n : j = 0, \dots, N-1\}$ and abbreviated as $\{\hat{\mathbf{x}}_j\}$, where n is the number of measured dofs. The (scaled) FFT of $\{\hat{\mathbf{x}}_j\}$ is the complex-valued sequence $\{F_k \in C^n : k = 0, \dots, N-1\}$ where

$$F_k = \sqrt{\frac{2\Delta t}{N}} \sum_{j=0}^{N-1} \hat{\mathbf{x}}_j \exp(-2\pi i j k / N) \quad (1)$$

$$k = 0, \dots, N-1$$

and $i^2 = -1$ and Δt is the sampling interval. For a given k , the FFT F_k corresponds to frequency

$$f_k = k / N \Delta t \quad k = 0, \dots, \text{int}[N/2] \quad (2)$$

where $\text{int}[N/2]$ is the integer part of $N/2$ and is the index corresponding to the Nyquist frequency.

The FFT F_k has been scaled so that $F_k F_k^* \in C^{n \times n}$ gives the one-sided sample spectral density (periodogram) matrix. Summing the i -th diagonal element of $F_k F_k^*$ over $k = 0, \dots, N-1$ and multiplying by the frequency resolution $\Delta f = 1/N \Delta t$ gives twice the mean square value of the i -th measured dof (Parseval equality).

For the purpose of identifying the modes of interest, it is sufficient and preferable to make use of the FFT data only on a selected frequency band around the mode(s). This is because in reality, the data contains a variety of dynamic (colored) activities over its sampling spectrum (up to the Nyquist frequency), most of which are irrelevant to identifying the mode(s) or are difficult to model.

Suppose there are m modes within the selected frequency band and let $\{F_k\}$ denote the collection of FFT data within the band. It is modeled as a sum of contributions from the structural vibration (the target to be measured) and a prediction error

(noise) that accounts for the difference between the theoretical and measured response:

$$F_k = \sum_{i=1}^m \Phi_i \ddot{\eta}_{ik} + \epsilon_k \quad (3)$$

where $\Phi_i \in R^n$ ($i = 1, \dots, m$) is the mode shape of the i -th mode in the selected frequency band; $\ddot{\eta}_{ik} \in C$ is the FFT at frequency f_k of the i -th modal acceleration response; and $\epsilon_k \in C^n$ is the FFT of the prediction error, which may arise due to measure (channel) noise and modeling error (e.g., unaccounted dynamics). Assuming classically damped modes, the time-domain counterpart of $\ddot{\eta}_{ik}$ satisfies the uncoupled equation of motion:

$$\ddot{\eta}_i(t) + 2\zeta_i \omega_i \dot{\eta}_i(t) + \omega_i^2 \eta_i(t) = p_i(t) \quad (4)$$

where $\omega_i = 2\pi f_i$; f_i , ζ_i , and $p_i(t)$ are, respectively, the natural frequency (in Hz), damping ratio, and modal force.

In the above context, the set of modal parameters to be identified from the FFT data $\{F_k\}$, denoted by θ , consists of the parameters:

- (1) Natural frequencies $f_1, \dots, f_m \in R^+$
- (2) Damping ratios $\zeta_1, \dots, \zeta_m \in (0, 1)$
- (3) Mode shapes $\Phi_1, \dots, \Phi_m \in R^n$
- (4) PSD matrix of modal forces $S \in C^{n \times n}$ (assumed constant within the band)
- (5) PSD of prediction error $S_e \in R^+$ (assumed constant within the band)

Each mode shape $\Phi_i = [\Phi_{1i}, \Phi_{2i}, \dots, \Phi_{ni}]^T$ is subjected to a unit norm constraint, i.e.,

$$\|\Phi_i\|^2 = \Phi_i^T \Phi_i = \sum_{j=1}^n \Phi_{ji}^2 = 1 \quad i = 1, \dots, m \quad (5)$$

Formulation from First Principle

In a Bayesian context, the information about the set of modal parameters θ that can be inferred from the FFT data $\{F_k\}$ is encapsulated in the “posterior probability density function” (PDF) of

θ , denoted by $p(\theta|\{F_k\})$. Using Bayes’ theorem, it is given by

$$p(\theta|\{F_k\}) = p(\{F_k\})^{-1} p(\{F_k\}|\theta) p(\theta) \quad (6)$$

The first term on the RHS does not depend on θ . As far as the identification of θ is concerned, it can be ignored. The middle-term $p(\{F_k\}|\theta)$ is called the “likelihood function.” It is derived based on modeling assumptions that relate the response of the theoretical model for a given θ to the FFT data. The middle-term $p(\theta)$ is the “prior distribution” that reflects one’s knowledge about θ in the absence of data. In modal identification problems with sufficient data, it can be taken as a constant because it is slowly varying compared to the likelihood function. As a result, it is sufficient for modal identification problems to use

$$p(\theta|\{F_k\}) \propto p(\{F_k\}|\theta) \quad (7)$$

Deriving the likelihood function requires deriving the joint PDF of $\{F_k\}$ for a given θ . This PDF is generally complicated, but it turns out to admit an asymptotic closed form when the number of data points N is large (Brillinger 1981). In particular, as $N \rightarrow \infty$, $\{F_k\}$ at different k ’s are asymptotically independent. For a given k , the real and imaginary parts of F_k are jointly Gaussian with zero mean. Thus,

$$p(\theta|\{F_k\}) \propto p(\{F_k\}|\theta) = (2\pi)^{-nN_f} \left[\prod_k \det C_k \right]^{-1/2} \exp \left\{ -\frac{1}{2} \sum_k \begin{bmatrix} \text{Re} F_k \\ \text{Im} F_k \end{bmatrix}^T C_k^{-1} \begin{bmatrix} \text{Re} F_k \\ \text{Im} F_k \end{bmatrix} \right\} \quad (8)$$

where the sum is overall frequency ordinates in the selected band, whose number is equal to N_f ; $C_k \in R^{2n \times 2n}$ is the covariance matrix of the augmented vector $[\text{Re} F_k; \text{Im} F_k] \in R^{2n}$; and $\det(\cdot)$ denotes the determinant of the argument matrix. For high sampling rate, it can be shown using random-vibration theory (Lutes and Sarkani 1997) that asymptotically

$$\mathbf{C}_k = \frac{1}{2} \begin{bmatrix} \Phi(\text{Re}\mathbf{H}_k)\Phi^T & -\Phi(\text{Im}\mathbf{H}_k)\Phi^T \\ \Phi(\text{Im}\mathbf{H}_k)\Phi^T & \Phi(\text{Re}\mathbf{H}_k)\Phi^T \end{bmatrix} + \frac{S_e}{2} \mathbf{I}_{2n} \quad (9)$$

where $\Phi = [\Phi_1, \dots, \Phi_m] \in R^{n \times m}$ is the mode shape matrix and $\mathbf{H}_k \in C^{m \times m}$ is the modal transfer matrix whose (i, j) entry is given by

$$\mathbf{H}_k(i, j) = S_{ij} h_{ik} h_{jk}^* \quad (10)$$

$$h_{ik} = [(\beta_{ik}^2 - 1) + (2\zeta_i \beta_{ik})\mathbf{i}]^{-1} \quad (11)$$

$$\beta_{ik} = f_i / f_k \quad (12)$$

and S_{ij} is the (i, j) entry of the PSD matrix of modal force, $\mathbf{S} \in C^{m \times m}$. Note that $\mathbf{H}_k$ and $\mathbf{S}$ are Hermitian (i.e., equal to its conjugate transpose); $\mathbf{C}_k$ is real symmetric.

Posterior Most Probable Value and Covariance Matrix

For convenience in analysis or computation, the posterior PDF is written in terms of the NLLF (negative log-likelihood function):

$$L(\boldsymbol{\theta}) = \frac{1}{2} \sum_k \text{Indet} \mathbf{C}_k + \frac{1}{2} \sum_k \begin{bmatrix} \text{Re} F_k \\ \text{Im} F_k \end{bmatrix}^T \mathbf{C}_k^{-1} \begin{bmatrix} \text{Re} F_k \\ \text{Im} F_k \end{bmatrix} \quad (13)$$

so that

$$p(\boldsymbol{\theta} | \{F_k\}) \propto \exp(-L(\boldsymbol{\theta})) \quad (14)$$

Note that the constant $nN_f \ln(2\pi)$ has been omitted from the NLLF.

With sufficient data often encountered in practice, the posterior PDF has a single peak in the parameter space of $\boldsymbol{\theta}$, which is the most probable value (MPV) of the modal parameters given the data. Equivalently, the NLLF has a unique minimum at the MPV. Approximating the NLLF by a second-order Taylor expansion about the MPV leads to a Gaussian approximation of the posterior PDF. The resulting Gaussian distribution has a mean at the MPV, and its covariance matrix, called the “posterior covariance matrix,” reflects the remaining uncertainties of the modal parameters

in the presence of the data. Mathematically, the posterior covariance matrix is equal to the inverse of the Hessian of the NLLF at the MPV.

The above results can be reasoned as follows. Given the data, let the MPV of the modal parameters be denoted by the vector $\hat{\boldsymbol{\theta}}$. Approximating the NLLF by a second-order Taylor expansion about $\hat{\boldsymbol{\theta}}$,

$$L(\boldsymbol{\theta}) \approx L(\hat{\boldsymbol{\theta}}) + \nabla L(\hat{\boldsymbol{\theta}})(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) + \frac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^T \nabla^2 L(\hat{\boldsymbol{\theta}})(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) \quad (15)$$

where $\nabla L(\hat{\boldsymbol{\theta}})$ and $\nabla^2 L(\hat{\boldsymbol{\theta}})$ denote, respectively, the gradient (row) vector and Hessian matrix of the NLLF at $\hat{\boldsymbol{\theta}}$. Since the NLLF is minimized at $\hat{\boldsymbol{\theta}}$, $\nabla L(\hat{\boldsymbol{\theta}}) = \mathbf{0}$ (a zero vector) and $\nabla^2 L(\hat{\boldsymbol{\theta}})$ are positive definite matrix. Applying this on Eq. 15 and then substituting into Eq. 14 gives

$$\begin{aligned} p(\boldsymbol{\theta} | \{F_k\}) &\propto \exp \left[-L(\hat{\boldsymbol{\theta}}) - \frac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^T \nabla^2 L(\hat{\boldsymbol{\theta}})(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) \right] \\ &\propto \exp \left[-\frac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^T \nabla^2 L(\hat{\boldsymbol{\theta}})(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) \right] \\ &\propto \exp \left[-\frac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^T \hat{\mathbf{C}}^{-1}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) \right] \end{aligned} \quad (16)$$

where

$$\hat{\mathbf{C}} = \nabla^2 L(\hat{\boldsymbol{\theta}})^{-1} \quad (17)$$

is a positive definite matrix. Eq. 16 is just the variable part of a joint Gaussian PDF with zero mean and covariance matrix equal to $\hat{\mathbf{C}}$. The proportionality constant of the equation is $(2\pi)^{-n_0/2} (\det \hat{\mathbf{C}})^{-1/2}$ (n_0 is the number of modal parameters), which can be obtained by integration or by probability reasoning. Thus,

$$\begin{aligned} p(\boldsymbol{\theta} | \{F_k\}) &= (2\pi)^{-n_0/2} (\det \hat{\mathbf{C}})^{-1/2} \\ &\exp \left[-\frac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^T \hat{\mathbf{C}}^{-1}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) \right] \end{aligned} \quad (18)$$

Computational Problems

The MPV of modal parameters cannot be obtained analytically because the relationship

between the NLLF and the modal parameters is complicated. Brute-force numerical minimization of the NLLF with respect to the modal parameters is prohibitive or not convergent, primarily because the number of modal parameters is typically large. The latter arises primarily from the number of measured dofs and secondarily from the number of modes. Taking into account the Hermitian nature of the PSD matrix of modal force, the number of modal parameters in $\boldsymbol{\theta}$ is equal to

$$n_{\theta} = (m + 1)^2 + nm \quad (19)$$

For example, a setup with 18 measured dofs and a band with $m = 2$ modes result in $(2 + 1)^2 + (18)(2) = 45$ parameters.

Adding to the difficulty is the ill-conditioned nature of the matrix $\mathbf{C}_k$ in Eq. 9. For good quality data, it is close to being rank deficient since it is then dominated by the first term, which has a rank of at most $2m$ and is often less than $2n$ (the number of modes m is often less than the number of measured dofs n).

Fast Equivalent Formulation

Using linear algebra techniques, it is possible to rewrite the NLLF in a form that facilitates analysis and computations. In particular, the NLLF can be written as a quadratic form of the mode shape, thereby allowing the most probable mode shape to be determined efficiently when the remaining parameters are given. Based on this, the MPV of all modal parameters can be obtained by optimizing different groups of parameters in turn, iterating until convergence.

Using the equivalent forms, analytical expressions for the Hessian of the NLLF can also be derived effectively. This allows the posterior covariance matrix to be evaluated efficiently and accurately, without resorting to finite difference method.

Single Mode

When there is only one mode in the selected band, the set of modal parameters reduces to

$$\boldsymbol{\theta} = \{f, \zeta, S, S_e, \boldsymbol{\Phi}\} \quad (20)$$

where mode index has been dropped for simplicity; $S \in R^+$ is the PSD of modal force; $\boldsymbol{\Phi} \in R^n$ is the mode shape.

It can be shown that the NLLF in Eq. 13 can be rewritten as

$$\begin{aligned} L(\boldsymbol{\theta}) = & -nN_f \ln 2 + (n - 1)N_f \ln S_e \\ & + \sum_k \ln(SD_k + S_e) \\ & + S_e^{-1} (d - \boldsymbol{\Phi}^T \mathbf{A} \boldsymbol{\Phi}) \end{aligned} \quad (21)$$

where

$$\mathbf{A} = \sum_k \left(1 + \frac{S_e}{SD_k} \right)^{-1} (\text{Re} F_k \text{Re} F_k^T + \text{Im} F_k \text{Im} F_k^T) \in R^{n \times n} \quad (22)$$

$$D_k = \left[(\beta_k^2 - 1)^2 + (2\zeta\beta_k)^2 \right]^{-1} \beta_k = f/f_k \quad (23)$$

$$d = \text{Re} F_k^T \text{Re} F_k + \text{Im} F_k^T \text{Im} F_k \quad (24)$$

Note that $\mathbf{A}$ depends on f, ζ, S, S_e ; D_k depends on f, ζ . The significance of Eq. 21 in comparison to Eq. 13 is that it no longer involves the inverse of ill-conditioned matrix. More importantly, the mode shape $\boldsymbol{\Phi}$ only appears in the quadratic form. Given the remaining parameters $\{f, \zeta, S, S_e\}$, minimizing the NLLF with respect to $\boldsymbol{\Phi}$ subjected to the norm constraint $\boldsymbol{\Phi}^T \boldsymbol{\Phi} = 1$ gives the most probable shape as the eigenvector of $\mathbf{A}$ with the largest eigenvalue. This effectively reduces the dimension of the optimization problem for MPV to only four (f, ζ, S, S_e), which can be readily performed numerically (Au 2011).

Multiple Modes

When there is more than one mode in the selected band, the set of modal parameters $\boldsymbol{\theta}$ is given by that stated in section Context, which is repeated here:

- (1) Natural frequencies $f_1, \dots, f_m \in \mathbb{R}^+$
- (2) Damping ratios $\zeta_1, \dots, \zeta_m \in (0, 1)$
- (3) Mode shapes $\Phi_1, \dots, \Phi_m \in \mathbb{R}^n$
- (4) PSD matrix of modal forces $\mathbf{S} \in \mathbb{C}^{n \times n}$
(assumed constant within the band)
- (5) PSD of prediction error $S_e \in \mathbb{R}^+$ (assumed constant within the band)

Each mode shape $\Phi_i = [\Phi_{1i}, \Phi_{2i}, \dots, \Phi_{ni}]^T$ is subjected to a unit norm constraint, i.e.,

$$\|\Phi_i\|^2 = \Phi_i^T \Phi_i = \sum_{j=1}^n \Phi_{ji}^2 = 1 \quad i = 1, \dots, m \quad (25)$$

In this case the most probable mode shape cannot be obtained directly by solving a standard eigenvalue problem. The mathematical structure of the optimization problem is more complex because the mode shapes are not necessarily orthogonal to each other. However, it is possible to reduce the complexity by representing the mode shape via a set of orthonormal basis and noting that the dimension of the subspace spanned by such basis does not exceed the number of modes. The mode shape matrix $\Phi = [\Phi_1, \dots, \Phi_m] \in \mathbb{R}^{n \times m}$ is represented as

$$\Phi = \mathbf{B}' \alpha \quad (26)$$

where

$$\mathbf{B}' = [\mathbf{B}'_1, \dots, \mathbf{B}'_{m'}] \in \mathbb{R}^{n \times m'} \quad (27)$$

contains in its columns a set of orthonormal “mode shape basis” $\{\mathbf{B}'_i \in \mathbb{R}^n : i = 1, \dots, m'\}$ spanning the “mode shape subspace;” $\alpha \in \mathbb{R}^{m' \times m}$ contains in its columns the coordinates of each mode shape with respect to the mode shape basis; $m' \leq \min(n, m)$ is the dimension of the mode shape subspace, which can be determined with the help of a singular-value spectrum. The MPVs of $\mathbf{B}'$ and α need to be determined in the identification process.

Based on Eq. 26, it can be shown that the NLLF can be rewritten as

$$\begin{aligned} L(\theta) = & -nN_f \ln 2 + (n - m')N_f \ln S_e \\ & + S_e^{-1}d + \sum_k \ln |\det \mathbf{E}'_k| \\ & - S_e^{-1} \sum_k F_k^* \mathbf{B}' (\mathbf{I}_{m'} - S_e \mathbf{E}'_k^{-1}) \mathbf{B}'^T F_k \end{aligned} \quad (28)$$

where d is given by Eq. 24 as in the case of single mode, and

$$\mathbf{E}'_k = \alpha \mathbf{H}_k \alpha^T + S_e \mathbf{I}_{m'} \quad (29)$$

is an m' -by- m' Hermitian matrix. The significance of Eq. 28 is that the mode shape basis $\mathbf{B}$ has been segregated out in the last term, which is quadratic in nature. The most probable basis should therefore minimize the quadratic form under orthonormal constraints. This does not lead to a standard eigenvalue problem, but procedures have been developed that allow the most probable basis to be determined efficiently by Newton iteration. This resolves the potentially high-dimensional optimization with respect to the mode shape. Based on this, a strategy has been developed for determining the MPV of different groups of parameters, iterating until convergence (Au 2012a).

Modal Signal-to-Noise Ratio

The term “signal-to-noise ratio” (s/n ratio) is often used to describe the quality of data to indicate the contribution of the signal targeted to be measured compared to the contribution of “noise,” which inevitably arises from sensor, cables transmitting the signal (especially for analog signals), digitizing hardware, etc. The actual quantitative definition differs depending on the particular application, however. In ambient modal identification, the s/n ratio that affects the identification results is related to the spectral contribution of the modal response compared to the spectral contribution of the noise in the vicinity of the resonance frequency band. In the case of well-separated modes, a definition of the s/n ratio that is found to govern fundamentally the

characteristics of the identification results is the PSD of the theoretical acceleration response at resonance ($SD_k = S/4\zeta^2$) divided by the PSD of the prediction error (S_e):

$$\gamma = \frac{S}{4S_e\zeta^2} \quad (30)$$

Governing Factors

The modal s/n ratio in Eq. 30 depends on the following factors:

- (1) The prediction error PSD S_e . This includes contributions from the channel noise as well as modeling errors, e.g., due to unaccounted modes and colored nature of modal force.
- (2) The damping ratio ζ . The smaller the damping, the higher the modal s/n ratio, as a result of higher modal response PSD at resonance.
- (3) The modal force PSD S . This in turn depends on the intensity of environmental excitation and (less trivially) on the measured dofs. Specifically, let ξ denote the “full” mode shape of the structure containing all (possibly an infinite number of) dofs, and it is scaled to have unit norm, i.e., $\xi^T \xi = 1$. Then it can be reasoned that

$$S = S_p \left(\sum_i \xi_i^2 \right) \quad (31)$$

where the sum is over the measured dofs, and

$$S_p = \frac{\xi^T \mathbf{S}_F \xi}{(\xi^T \mathbf{M} \xi)^2} \quad (32)$$

is the modal force PSD consistent with the scaling of the global mode shape ξ ; $\mathbf{M}$ is the mass matrix of the structure. Note that in reality, the full mode shape ξ and the mass matrix $\mathbf{M}$ can hardly be identified and so is S_p . Instead, the measured mode shape Φ and the modal force PSD S consistent with the scaling $\Phi^T \Phi = 1$ is identified. Eq. 31 shows that the modal force PSD S always increases with the number of measured dofs, although the rate depends on the mode shape of the dof incrementally added to the existing set of measured dofs. As a result, the

modal s/n ratio in Eq. 30 always increases with the number of measured dofs.

High s/n Asymptotics

It turns out that the Bayesian modal identification results in terms of the MPV and posterior covariance matrix reduce to intuitive forms when the modal s/n ratio is large (theoretically infinity). This is referred to as “high s/n asymptotics.”

Asymptotically for large modal s/n ratio, the terms in the NLLF can be separated into two terms: one quadratic term depending only on the mode shape (and the prediction error PSD in a multiplicative manner) and the other term depending only on the remaining parameters (natural frequency, damping ratio, modal force PSD, prediction error PSD). The mode shapes are therefore asymptotically uncoupled from the remaining parameters. This has important implications on the behavior of the MPV and the posterior covariance matrix. The former provides a sound basis for setting initial guess and designing fast algorithms for determining the MPV of modal parameters. The latter leads to remarkably simple closed-form formulas for the posterior variance of the modal parameters. These are collectively known as “uncertainty laws,” which govern the achievable limits of operational modal analysis.

The asymptotic behavior of the most probable mode shape is discussed in sections [Single Mode](#) and [Multiple Modes](#) for a single mode and multiple modes in the selected frequency band, respectively. The posterior covariance matrix is discussed in the context of uncertainty laws in section [Uncertainty Laws](#).

Single Mode

For a single mode in the selected band, asymptotically the most probable mode shape Φ is equal to the eigenvector with the largest eigenvalue of the following matrix:

$$\mathbf{A}_0 = \sum_k (\text{Re} F_k \text{Re} F_k^T + \text{Im} F_k \text{Im} F_k^T) \quad (33)$$

This matrix depends only on the data, and so the most probable mode shape can be calculated explicitly without optimization.

The above result can be reasoned as follows. Asymptotically the matrix $\mathbf{A}$ in the NLLF Eq. 21 becomes $\mathbf{A}_0$ in Eq. 33, and so the NLLF becomes

$$\begin{aligned} L(\boldsymbol{\theta}) \sim & -nN_f \ln 2 + (n-1)N_f \ln S_e \\ & + \sum_k \ln(SD_k + S_e) + S_e^{-1}d \\ & - S_e^{-1} \boldsymbol{\Phi}^T \mathbf{A}_0 \boldsymbol{\Phi} \end{aligned} \quad (34)$$

In the above expression, only the last term depends on $\boldsymbol{\Phi}$, which is a quadratic form with a constant coefficient matrix $\mathbf{A}_0$. Minimizing it with respect to $\boldsymbol{\Phi}$ and subjected to the norm constraint $\boldsymbol{\Phi}^T \boldsymbol{\Phi} = 1$ gives the most probable mode shape as the eigenvector of $\mathbf{A}_0$ with the largest eigenvalue.

Multiple Modes

When there is more than one mode in the selected band, asymptotically the most probable mode shape basis is given by the eigenvectors of $\mathbf{A}_0$ in Eq. 33 corresponding to the first m' largest eigenvalues. Note that this does not give directly the most probable mode shapes because the MPV of the coordinates with respect to the basis, i.e., $\boldsymbol{\alpha}$ in Eq. 26, is not known but its determination is still nontrivial.

The above can be reasoned as follows. Asymptotically, the term $(\mathbf{I}_{m'} - S_e \mathbf{E}'_k)$ in the quadratic term of the NLLF in Eq. 28 becomes the identity matrix $\mathbf{I}_{m'}$ and so

$$\begin{aligned} L(\boldsymbol{\theta}) \sim & -nN_f \ln 2 + (n-m')N_f \ln S_e \\ & + S_e^{-1}d + \sum_k \ln|\det \mathbf{E}'_k| \\ & - S_e^{-1} \sum_k F_k^* \mathbf{B}' \mathbf{B}'^T F_k \end{aligned} \quad (35)$$

This expression depends on the mode shape basis $\mathbf{B}'$ only through the sum in the last term, which is quadratic in nature. Substituting $\mathbf{B}' = [\mathbf{B}'_1, \dots, \mathbf{B}'_{m'}]$, the sum can be rewritten as

$$\begin{aligned} \sum_k F_k^* \mathbf{B}' \mathbf{B}'^T F_k &= \sum_{i=1}^{m'} \mathbf{B}'_i{}^T \left(\sum_k F_k F_k^* \right) \mathbf{B}'_i \\ &= \sum_{i=1}^{m'} \mathbf{B}'_i{}^T \mathbf{A}_0 \mathbf{B}'_i \end{aligned} \quad (36)$$

Minimizing the NLLF is equivalent to maximizing the sum on the rightmost. Since it contains no cross terms between $\mathbf{B}'_i$ and $\mathbf{B}'_j$ ($i \neq j$), maximizing it gives the most probable basis as the eigenvectors of $\mathbf{A}_0$ corresponding to the first m' largest eigenvalues.

Quantification of Identification Uncertainty

Mode Shape Uncertainty

For scalar-valued modal parameters such as the natural frequency and damping ratio, the posterior uncertainty can be conveniently described in terms of the posterior standard deviation or in a nondimensional manner the posterior coefficient of variation (c.o.v.), equal to the posterior standard deviation divided by the MPV. The posterior standard deviation is equal to the square root of the posterior variance, which can be obtained from the corresponding diagonal entry of the posterior covariance matrix.

The above quantification cannot be applied to the mode shape because it is vector valued and is subject to the norm constraint. One way to quantify the uncertainty of the mode shape is through the Expected modal assurance criterion (MAC), defined analogously as in the deterministic case. According to the posterior distribution, which is approximated by a Gaussian distribution, given the measured data, the mode shape is a Gaussian vector with mean vector equal to the most probable mode shape and a covariance matrix $\mathbf{C}_\Phi \in R^{n \times n}$. The latter is given by the corresponding $n \times n$ partition of the full covariance matrix (containing all modal parameters). The Expected MAC is defined as the expected value of the cosine of the hyper angle between the random mode shape vector and the most probable mode shape vector. This value ranges between 0 and 1; the higher the value, the smaller the mode shape uncertainty. An exact closed-form expression for the Expected MAC has not been developed, but an asymptotic expression is available, which is adequate for practical purposes. It can be shown that asymptotically

$$\text{Expected MAC} = \left(1 + \sum_{i=2}^n \kappa_i^2\right)^{-1/2} \quad (37)$$

where $\{\kappa_i : i = 1, \dots, n\}$ are the eigenvalues (principal variances) of the posterior covariance matrix of the mode shape, $\mathbf{C}_\Phi$. This formula is asymptotically correct for small $\{\kappa_i\}$ or large n . The sum does not contain κ_1 because it is theoretically equal to zero, resulting from the norm constraint on the mode shape Au 2011.

In well-controlled ambient tests, the Expected MAC is often close to 1. A complementary measure of the mode shape uncertainty is the expected value of the hyper angle between the random mode shape vector and the most probable mode shape vector. It can be shown that under the same asymptotic conditions in Eq. 37, the expected value of the hyper angle is given by

$$\delta_\Phi = \left(\sum_{i=2}^n \kappa_i^2\right)^{1/2} \quad (38)$$

and it is related to the Expected MAC by

$$\text{Expected MAC} = 1 - \frac{1}{2} \delta_\Phi^2 \quad (39)$$

Bayesian Versus Non-Bayesian Measure

Bayesian Measure

In the context of Bayesian system identification, the spread of the posterior PDF is a direct fundamental quantification of the remaining uncertainty associated with the modal parameters for a given assumed identification model and in the presence of the measured data. Since the posterior PDF is typically unimodal and it can be approximated by a joint Gaussian PDF, the uncertainty of the modal parameters can be quantified by the covariance matrix, which is called the “posterior covariance matrix.” The posterior covariance matrix is the inverse of the Hessian matrix of the NLLF, and it can be calculated for a given set of data. Clearly it depends on the particular set of data.

Non-Bayesian Measure

In non-Bayesian identification methods, the identification results are often given in terms of the “best” or “optimal” value calculated from an accepted algorithm. This is analogous to the MPV calculated in a Bayesian identification method. In a non-Bayesian context, one conventional quantification of the uncertainty of the identified parameters is through the ensemble variance (or more generally, the ensemble covariance matrix) of the modal parameters. This can be understood as the variance among the identified (i.e., best) values calculated from a large (theoretically infinite) number of repeated experiments. This is a “frequentist” measure of the uncertainty of the identified parameters. Unlike the posterior variance that is defined for a given set of data, the ensemble variance requires (at least conceptually) the notion of repeated experiments. Because of its ensemble nature, it does not depend on a particular data set. If there were no modeling error, i.e., the data in the repeated experiments indeed results from a process obeying the identification model assumed, the variability of the identified values among repeated experiments reflects the quality of the identification algorithm and the amount of data used. Otherwise, it reflects also the variability due to other factors such as the changes in system properties among the experiments and modeling errors.

Connection

Due to their different definitions, the Bayesian and frequentist measure of the identification uncertainty of modal parameters need not coincide, although intuition suggests that they should be of similar order of magnitude when there is no modeling error. It can be shown that when there is no modeling error then in a weighted sense, the expectation of the posterior covariance matrix (Bayesian) is equal to the ensemble variance of the most probable value among repeated experiments (Au 2012b). In reality where modeling error can exist and conditions can change among the repeated experiments, the Bayesian and frequentist measure can differ significantly.

The Bayesian and frequentist measure of identification uncertainty has different roles. The Bayesian measure reflects fundamentally the remaining uncertainty associated with the parameters for a given identification model and a given set of data. It does not reflect what the identification results would be if the experiment is repeated, because modeling error can exist and conditions of the next experiment can change. It does not describe ensemble variability. On the other hand, the frequentist measure is an aggregate effect of identification uncertainty, modeling error, and system changes over the repeated experiments.

Uncertainty Laws

Under the Bayesian framework, the posterior uncertainty of the modal parameters can be calculated in terms of the posterior covariance for a given set of measured data. This process is computational and implicit in nature. It does not yield much insight about how the identification uncertainty depends on test configurations.

In the case of a single mode in the selected band, it has been possible to derive closed-form analytical expressions for the posterior covariance matrix under asymptotic conditions, namely, small damping and long data duration, which are typically met in applications. The expressions are collectively referred as “uncertainty laws” (Au 2014a, b). They provide insights on the scientific nature of the ambient modal identification problem and its fundamental limits on identification uncertainty. The uncertainty laws can also be used for drafting specifications for ambient vibration tests.

Context

The uncertainty laws have been derived under the following context:

- (1) The damping ratio is small, $\zeta \rightarrow 0$.
- (2) The spectral information for identifying the mode is large, in the sense that $N_f = 2\kappa\zeta N_c \rightarrow \infty$ where $N_c = T_d/T$, T_d is

the data duration, and T is the natural period of the target mode. Note that $N_f \rightarrow \infty$ and $\zeta \rightarrow 0$ imply that $N_c \rightarrow \infty$ as well.

- (3) The selected frequency band is assumed to be $f(1 \pm \kappa\zeta)$, where κ is called the “bandwidth factor.” The bandwidth factor is a trade-off between identification information (the larger, the better) and modeling error risk (the smaller, the better). Typically it ranges between 3 and 10.
- (4) The FFT data $\{F_k\}$ in the selected band is assumed to indeed result from a process obeying the identification model, i.e., no modeling error. Note that prediction error is still present because it is part of the identification model.

The selected frequency bandwidth is assumed to be proportional to the damping ratio because the width of the resonance band around the natural frequency does, e.g., the half power band is $f(1 \pm \zeta)$, corresponding to $\kappa = 1$. An asymptotically small damping ratio implies that the modal s/n ratio $\gamma = S/4S_e\zeta^2$ in Eq. 30 is asymptotically high. It is therefore implied in the uncertainty laws that the modal s/n ratio is high.

Main Results

The asymptotic expressions of the posterior coefficient of variation of the modal parameters are summarized in Table 1. In terms of correlation, except for that between the damping ratio ζ and the modal force PSD S , the correlation between any pair of the modal parameters among $\{f, \zeta, S, S_e, \Phi\}$ is asymptotically small, at most $O(\zeta)$. The correlation between ζ and S is $O(\kappa^{-1/2})$.

Implications

The following implications can be drawn from the uncertainty laws:

- (1) For small damping ratio, the posterior uncertainties of the natural frequency and mode shape are significantly smaller than those of the damping ratio and the modal force PSD. The former are $O(\zeta^{1/2})$ and the latter are $O(\zeta^{-1/2})$.

Bayesian Operational Modal Analysis, Table 1 Summary of uncertainty laws

Parameter	Uncertainty law	Bandwidth factor
Frequency f	Squared posterior c.o.v. $\delta_f^2 = \frac{\zeta}{2\pi N_c B_f(\kappa)}$	$B_f(\kappa) = \frac{2}{\pi} \left(\tan^{-1} \kappa - \frac{\kappa}{\kappa^2 + 1} \right)$
Damping ζ	Squared posterior c.o.v. $\delta_\zeta^2 = \frac{1}{2\pi \zeta N_c B_\zeta(\kappa)}$	$B_\zeta(\kappa) = \frac{2}{\pi} \left[\tan^{-1} \kappa + \frac{\kappa}{\kappa^2 + 1} - \frac{2(\tan^{-1} \kappa)^2}{\kappa} \right]$
Modal force PSD S	Squared posterior c.o.v. $\delta_S^2 = \frac{1}{N_f B_S(\kappa)}$	$B_S(\kappa) = 1 - \frac{2}{\kappa} (\tan^{-1} \kappa)^2 \left(\tan^{-1} \kappa + \frac{\kappa}{\kappa^2 + 1} \right)^{-1}$
Prediction error PSD S_e	Squared posterior c.o.v. $\delta_{S_e}^2 = \frac{1}{(n-1)N_f}$	—
Mode shape Φ	Covariance matrix $\mathbf{C}_\Phi = \frac{v_\zeta^2}{N_c B_\Phi(\kappa)} (\mathbf{I}_n - \Phi \Phi^T)$ Expected hyper angle (squared) $\delta_\Phi^2 = \frac{(n-1)v_\zeta^2}{N_c \tan^{-1} \kappa}$	$B_\Phi(\kappa) = \tan^{-1} \kappa$

- (2) The damping ratio has the greatest uncertainty in terms of posterior c.o.v. and is therefore expected to govern the accuracy requirement in ambient vibration tests.
- (3) The mode shape is the only modal property whose leading order uncertainty is affected by the modal s/n ratio. Its posterior uncertainty is typically small. This implies that in reality the quality of the mode shape is likely to be governed by other sources such as sensor alignment error.
- (4) When the modal s/n ratio is high, reducing the channel noise level (e.g., with better equipment) or increasing the measured dofs has little or no effect on reducing the posterior c.o.v.s of modal parameters. It is because these factors influence only the modal s/n ratio, but the latter has no role in the uncertainty laws.
- (5) Assuming a damping ratio of 1 % and a bandwidth factor of 6, the minimum data duration to achieve a posterior of c.o.v. of 30 % in the damping ratio is 300 natural periods.

Summary

A Bayesian approach for modal identification provides a fundamental means for processing the information contained in the data to make inference on the modal parameters consistent

with probability logic and modeling assumptions. This is especially relevant for ambient modal identification where the input excitation is not measured and where significant uncertainty can exist in the identified modal parameters even in the presence of data. A frequency domain approach is preferred over a time-domain approach because it significantly relaxes the broadband assumption on the modal force and prediction error. By making inference using the FFT on a selected frequency band around the mode of interest, the modal force and prediction error only need to have a flat spectrum within the band. The likelihood function can be formulated from first principles using random-vibration theory and signal processing asymptotics. The resulting form, however, does not allow the posterior statistics of the modal parameters to be computed easily because its dependence on the modal parameters is complicated and there are typically a moderate to large number of parameters. Using linear algebra techniques, fast equivalent formulations have been developed that allow efficient algorithms to be developed. The Bayesian identification results are governed characteristically by the modal signal-to-noise ratio. The posterior covariance matrix also admits remarkably simple closed form when the s/n ratio is high, leading to a set of uncertainty laws that govern the limit of ambient modal identification.

Introduction

Bayesian statistics are related to Bayes' rule after Thomas Bayes, a Presbyterian minister, probably born in 1701. Thomas Bayes' fame rests in his paper "An Essay Towards Solving a Problem in the Doctrine of Chances" communicated to the Royal Society in 1763, after his death in 1761, by his friend Richard Price (1723–1791) (Bellhouse 2004). Bayes addresses the following question in his essay: "Given the number of times in which an unknown event has happened and failed: Required the chance that the probability of its happening in a single trial lies somewhere between any two degrees of probability that can be named (Bayes (1763), p. 376)" (Dale 1986; Edwards 1978). The question is answered in its famous Bayes' model table problem (Bellhouse 2004).

Gillies (1987) calls this problem "Bayes' billiard table example." The problem assumes a unit-square table and two balls O and W. The ball W is thrown across the table once, and its rest point defines level p with respect to one of the sides of the table. The ball O is then thrown n times, and it is said that if ball O stops below level p , the event is a success. If we call the number of successes r , then the probability that ball O will stop between levels a and b is given by

$$\frac{\int_a^b x^r (1-x)^{n-r} dx}{\int_0^1 x^r (1-x)^{n-r} dx}.$$

As Bayes' rule becomes popular in many fields of science and engineering, earthquake engineering problems began to be solved in the Bayesian framework. One of the first Bayesian approaches on site seismicity is proposed in Esteva (1969) for the rate of seismic event occurrence and later in Suzuki and Kiremidjian (1991). The Bayesian framework is also used in other seismology-related areas to update ground motion prediction models' parameters to new data in Wang and Takada (2009) and Atkinson and Boore (2011). Earthquake engineering also deals with the probabilistic assessment of the structural response

under seismic loads. The probability of structural response to exceed critical states is known as seismic fragility. Early papers by Goodman (1986) and Mosleh and Apostolakis (1986) deal with failure and fragility analyses in a Bayesian context. Recently, the Bayesian framework has been used in a wide range of applications for calculating fragility curves (Straub and Kiureghian 2008; Koutsourelakis 2010).

Bayes' rule stays at the basis of the Bayesian framework and is a statement of conditional probability. It provides information on the probability of unknown parameters $\Theta = [\theta_1, \dots, \theta_n]$ given some data x ,

$$p(\Theta|x) \propto f(\Theta)l(\Theta|x), \quad (1)$$

where $f(\Theta)$ and $p(\Theta|x)$ are referred to as the *prior* and *posterior* probability density functions of Θ and $l(x|\Theta)$ is called the *likelihood* function, which accounts for the significance of the observed data x on the distribution of Θ (Gelman et al. 2003). The prior probability density function $f(\Theta)$ should contain all possible values of Θ . The probability associated with the values of Θ , i.e., $f(\Theta)$, can be interpreted as the current knowledge about Θ . When all the values of the unknown parameters Θ are assumed to be equally likely, we call the prior *non-informative*. If the prior and the posterior densities have the same functional form for the probability distributions, we refer to the prior as a *conjugate prior*.

Sampling from the posterior distribution of Θ may be challenging. Direct sampling from $p(\Theta|x)$ in the case of non-conjugate prior densities is even more difficult, and sampling techniques have been developed. Markov Chain Monte Carlo (MCMC) is a general algorithm of drawing samples of Θ from a random distribution $p(\Theta|x)$.

Applications of the Bayesian theory in earthquake engineering are shown in the next section. Bayesian Framework in Earthquake Engineering

Seismic Hazard Analysis

Earthquake Probabilities

A seismic activity matrix is defined as a two-dimensional histogram which gives the probability of occurrence p_j of earthquakes characterized by moment magnitude m and source-to-site distance r , denoted by $(m, r)_j$. Each point in this matrix with coordinates $(m, r)_j$ is referred to as a cell $j = 1, \dots, n_c$, where n_c is the total number of cells. Note that $\sum_{j=1}^{n_c} p_j = 1$. Seismic activity matrices can be calculated for each zip code in the United States by using the earthquake probability tool available on the US Geological Survey website (USGS 2009). Figure 1 shows the seismic activity matrix for Los Angeles.

A Bayesian approach is used to update earthquake probabilities in light of new data. For this, we seek a probabilistic parametric model with parameters, the earthquake probabilities. Let Z_j be a random variable which counts the number of new earthquakes recorded in each cell j . The vector $\mathbf{Z} = \{Z_j, j = 1, \dots, n_c\}$ has a

multinomial distribution with parameters $\Theta = \{\theta_j, j = 1, \dots, n_c\}$, a random vector whose coordinates θ_j capture earthquake probabilities in each cell j , such that $\sum_{j=1}^{n_c} \theta_j = 1$. We call $N_Z = \sum_{j=1}^{n_c} Z_j$ the total number of newly recorded earthquakes. The new records are used in the Bayesian framework to update earthquake probabilities p_j .

Numerical example. For illustration, a hypothetical example is considered. It is assumed that at a site only three earthquakes $j = 1, 2, 3$ are likely to occur with known probabilities $p_1 = 0.2, p_2 = 0.3, p_3 = 0.5$. The seismic activity matrix, shown in Fig. 3a, has $n_c = 3$ cells. If an earthquake of type $j = 1$ occurs at that site and it is used for the update of the earthquake probabilities p_1, p_2, p_3 , then $N_Z = 1$ and $\mathbf{z} = [z_1 \ z_2 \ z_3] = [1 \ 0 \ 0]$, which is a sample of $\mathbf{Z}$.

The unknown parameters $\{\theta_1, \dots, \theta_{n_c}\}$ are assumed to have a Dirichlet distribution with parameters $\{\alpha_1, \dots, \alpha_{n_c}\}$, that is,

$$f(\theta_1, \dots, \theta_{n_c}) \propto \prod_{j=1}^{n_c} \theta_j^{\alpha_j-1}, \forall \theta_j \geq 0. \quad (2)$$

Moreover, we impose that

$$\mathbb{E}[\theta_j] = \frac{\alpha_j}{\alpha_0} = p_j, \quad (3)$$

Bayesian Statistics: Applications to Earthquake Engineering,

Fig. 1 Seismic activity matrix for Los Angeles

Bayesian Statistics: Applications to Earthquake Engineering, Fig. 2 (a) Prior density $f(\theta_1, \theta_2, 1 - \theta_1 - \theta_2)$ and (b) posterior density $p(\theta_1, \theta_2, 1 - \theta_1 - \theta_2 | \mathbf{z})$

in order to reflect the prior knowledge from the seismic activity matrix, where $\alpha_0 = \sum_{j=1}^{n_c} \alpha_j$. For a given value of α_0 , parameters $\alpha_j = p_j \alpha_0$ have deterministic values, and they are known as hyper-parameters. The value α_0 can be interpreted as the total number of recorded earthquakes to have occurred at the site until the new earthquakes in $\mathbf{Z}$ were recorded.

Based on the assumption that $\mathbf{Z}$ has a multinomial distribution, the likelihood function is written as

$$l(\mathbf{z} | \Theta) = \prod_{j=1}^{n_c} \theta_j^{z_j}. \quad (4)$$

The posterior probability density of the unknown parameters Θ is calculated as shown in Eq. 1:

$$p(\Theta | \mathbf{z}) = \prod_{j=1}^{n_c} \theta_j^{\alpha_j + z_j - 1}, \quad (5)$$

which is also a Dirichlet distribution with parameters $\alpha_j + z_j, j = 1, \dots, n_c$. Note that the Dirichlet distribution is the conjugate prior of the multinomial distribution. The seismic activity matrix in light of new data is, then, given by the expectation of Θ :

$$\mathbb{E}[\theta_j] = \frac{\alpha_j p_j + z_j}{\alpha_0 + n_z}. \quad (6)$$

For the hypothetical case presented above, the prior density $f(\theta_1, \theta_2, \theta_3)$ and the posterior density $p(\theta_1, \theta_2, \theta_3 | \mathbf{z})$ are shown in Fig. 2 in the form of $f(\theta_1, \theta_2, 1 - \theta_1 - \theta_2)$ and $p(\theta_1, \theta_2, 1 - \theta_1 - \theta_2 | \mathbf{z})$, respectively, since $\theta_1 + \theta_2 + \theta_3 = 1$. The results are shown for $\alpha_0 = 10$.

The updated seismic activity matrix with the new data $\mathbf{z}$, i.e., $\mathbb{E}[\Theta | \mathbf{z}]$, is shown in Fig. 3b.

Seismological Model Update

The specific barrier model (Halldorsson and Papageorgiou 2005) is a source model which characterizes the frequency content of the ground motion process in the form of a function $g(v; (m, r)_j)$ of $(m, r)_j$, called power spectral density. The specific barrier model is calibrated to regional data and cannot provide information about ground motions at particular sites. For simplicity, the following notation $g_j(v) := g(v; (m, r)_j)$ is used.

A Bayesian framework is used to update the spectral density model with site-specific records (Radu and Grigoriu 2014). The power spectral density function $g_j(v)$ is only available in

Bayesian Statistics: Applications to Earthquake Engineering, Fig. 3 Two-dimensional seismic activity matrix: (a) original earthquake probabilities $p_j, j = 1, 2, 3$, and (b) updated earthquake probabilities $\mathbb{E}[\theta_j|\mathbf{z}], j = 1, 2, 3$

Bayesian Statistics: Applications to Earthquake Engineering, Fig. 4 (a) Power spectral density $g_j(v)$ and (b) linear components $\varphi_{k,j}, k = 1, 2, 3$, for $(m, r)_j = (8, 200 \text{ km})$

algorithmic form. For the Bayesian approach, a parametric model for $g_j(v)$ is sought, and it is written as

$$g_j(v : \Theta) = \theta_1 \varphi_{1,j} + \theta_2 \varphi_{2,j} + \theta_3 \varphi_{3,j} \quad (7)$$

using the singular value decomposition, where $\{\theta_k = 1, k = 1, 2, 3\}$ are some global parameters and $\varphi_{k,j}, k = 1, 2, 3$, are deterministic

functions which depend on $(m, r)_j$. In the Bayesian context, the vector $\Theta = \{\theta_k, k = 1, 2, 3\}$ is seen as a random vector with mean $\mathbb{E}[\Theta] = [111]$. The range Ψ of Θ is defined such that it ensures the existence of the spectral density, i.e., $g_j(v) \geq 0, \forall_j = 1, \dots, n_c, \forall v \geq 0$, and $\forall \theta \in \Psi$. A uniform prior $f(\Theta)$ on Ψ is assumed for the vector of unknown parameters Θ . Figure 4 shows the spectral density $g_j(v)$ for $(m, r)_j = (8, 200 \text{ km})$ and its components $\varphi_{k,j}, k = 1, 2, 3$.

**Bayesian Statistics:
Applications to
Earthquake Engineering,**
Fig. 5 Marginal prior and
posterior densities for (a)
 θ_1 , (b) θ_2 , and (c) θ_3

Let $\mathbf{x} = \{x_{j,i}, i = 1, \dots, n_j, j = 1, \dots, n_c\}$ be a set of $n = \sum_{j=1}^{n_c} n_j$ ground motion records available at a site, where n_j is the number of earthquakes with $(m, r)_j$ and n_c is the number of cells in the seismic activity matrix in Fig. 1. It is assumed that $x_{j,i}$ are the discrete versions of the records' strong motion parts, i.e., the part of the earthquake where most of its energy is concentrated (Trifunac 1971). Under the assumption that $x_{j,i}$ are samples of a zero-mean, stationary, Gaussian process (Zerva 2009), Chap. 7; Rezaeian and Kiureghian 2010), the logarithmic form of the likelihood function is written as

$$\ln(l(\mathbf{x}|\Theta)) \propto -\frac{n}{2} \ln(|C_j(\Theta)|) - \frac{1}{2} \sum_{i=1}^{n_c} \sum_{j=1}^{n_j} x_{j,i}^T C_j(\Theta)^{-1} x_{j,i}, \quad (8)$$

where $\ln$ denotes the natural logarithm and $|C_j(\Theta)|$ is the determinant of the covariance

matrix $C_j(\Theta)$ of the ground motion process in cell j . The components of the covariance matrix can be calculated from the Fourier transform of the spectral density function $g_j(v; \Theta)$ (Grigoriu 2012, Section 3.6).

The posterior probability density function $p(\Theta | \mathbf{x})$ follows directly from Eq. 1.

Numerical example. For numerical results, $n = 5,000$ samples of zero-mean, stationary, Gaussian processes with spectral densities $g_j(v)$, $j = 1, \dots, n_c$, were simulated in cells j according to the multinomial distribution given by the seismic activity matrix of Los Angeles (Fig. 1). The marginal prior and posterior densities of the unknown parameters θ_i , $i = 1, 2, 3$ are shown in Fig. 5.

The resulting posterior 95 % confidence interval for the spectral density $g_j(v; \Theta)$ shown in Fig. 6, i.e., the interval $[g_j^{lw}(v), g_j^{up}(v)]$ such that $\mathbb{P}\{g_j(v; \Theta) \in [g_j^{lw}(v), g_j^{up}(v)]\} = 0.95$, is also calculated based on the density $p(\Theta | \mathbf{x})$.

Bayesian Statistics: Applications to Earthquake Engineering, Fig. 6 Ninety-five percent confidence interval (CI) for the spectral density $g_j(\nu; \Theta)$, $j = 1, 2, 3$

Seismic Fragility Analysis

Seismic fragility of a structural or nonstructural system is the probability that the system's response exceeds a critical value under seismic ground motions of specified intensities, e.g., peak ground acceleration (PGA) or pseudo-spectral acceleration (PSa) (Kafali and Grigoriu 2010). Graphical representations of seismic fragilities are called fragility curves.

Reliable fragility analyses require the use of large numbers of seismic records, which are not usually available. Thus, Monte Carlo simulations of synthetic seismic motions or scaling of actual records to common intensity measures are among the most popular methods. The Bayesian framework allows calculation of seismic fragility curves using just the data available.

It is assumed that n ground motion records $x_i(t)$, $i = 1, \dots, n$, are available at a site. The response displacement $y_i(t)$ of a system to record $x_i(t)$ is characterized by a second-order differential equation:

$$y_i'' = D(y_i, y_i', x_i), \quad (9)$$

where D can be either a linear or a nonlinear operator. For example, for a linear single-degree-of-freedom system with frequency ω_0 and damping ratio ζ_0 ,

$$D(y_i, y_i', x_i) = -(2\omega_0\zeta_0 y_i' + \omega_0^2 y_i + x_i). \quad (10)$$

Two intensity measures for the ground motion $x_i(t)$ are defined:

1. Peak ground acceleration (PGA)

$$\xi_i = \max_{0 \leq t \leq \tau} |x_i(t)| \quad (11)$$

2. Pseudo-spectral acceleration (PSa)

$$\xi_i(\omega; \zeta) = \max_{0 \leq t \leq \tau} |y_i(t; \omega, \zeta)|, \quad (12)$$

where $y_i(t; \omega, \zeta)$ is the solution of Eq. 10.

For illustration purposes, we present the methodology for calculating fragility curves for the single-degree-of-freedom system in Eq. 10. In this context, we define the seismic fragility as

$$P_f(\zeta; y_{cr}) = \mathbb{P} \left(\max_{0 \leq t \leq \tau} |y_i(t; \omega_0, \zeta_0)| > y_{cr} \mid \xi_i = \zeta \right), \quad (13)$$

where y_{cr} is a critical displacement imposed for the system. Fragility curves can be calculated for any other engineering design parameters, e.g., the inter-story drift in the case of multi-degree-of-freedom systems. For simplicity, parameters y_{cr} is dropped from notation $P_f(\zeta; y_{cr})$.

In order to calculate fragility curves in a Bayesian framework, a parametric model for $P_f(\zeta)$ is sought. Fragility curves are increasing functions plotted against positive ground motion intensity measures $\zeta > 0$ and left-bounded at zero.

Therefore, it is common to assume that they are well modeled by log-normal cumulative distribution functions $F(\zeta; \mu, \sigma)$ with mean μ and standard deviation σ . The log-normal cumulative distribution function is defined as

$$F(\zeta; \mu, \sigma) = \int_0^{\zeta} \phi_{LN}(x; \mu, \sigma) dx, \quad (14)$$

Bayesian Statistics: Applications to Earthquake Engineering, Fig. 7 Three-dimensional and corresponding contour plots for the posterior density functions of $(\mu_{PGA}, \sigma_{PGA})$, for (a), (c) $n = 10$ and (b), (d) $n = 50$ records

where

$$s_i = 1\{y_i(t) > y_{cr}\}, \quad (16)$$

$$\phi_{LN}(x; \mu, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} \exp\left\{-\frac{(\ln(x) - \mu)^2}{2\sigma^2}\right\}, x > 0, \quad (15)$$

and $\phi_{LN}(x; \mu, \sigma)$ is the probability density function of the log-normal distribution with mean $\mu \in \mathbb{R}$ and standard deviation $\sigma \geq 0$.

The model for the fragility curve in Eq. 13 is $P_f(\xi; \Theta) = F(\xi; \mu, \sigma)$, where $\Theta = (\mu, \sigma)$ is the vector of unknown parameters to be estimated from the data. Parameters (μ, σ) define uniquely the fragility curve.

A non-informative uniform prior $f(\Theta)$ is assumed for $\Theta = (\mu, \sigma)$ in a custom range within previously defined bounds, i.e., $\mu \in \mathbb{R}, \sigma \geq 0$.

Let $s = \{s_i, i = 1, \dots, n\}$ be a vector with values:

where 1 denotes the indicator function. The vector s is a sample of a binomial random vector with parameters $(n, \{F(\xi_i; \mu, \sigma), i = 1, \dots, n\})$. Then, the likelihood function is defined as

$$l(s|\mu, \sigma) = \prod_{i=1}^n (1 - F(\xi; \mu, \sigma))^{1-s_i} F(\xi; \mu, \sigma)^{s_i}. \quad (17)$$

Finally, the posterior density of parameters Θ is

$$p(\mu, \sigma|s) \propto f(\mu, \sigma) l(s|\mu, \sigma). \quad (18)$$

Numerical examples Numerical examples are shown for the linear single-degree-of-freedom system in Eq. 10 with $\omega_0 = \pi \text{ rad/s}$, $\zeta_0 = 2\%$,

Bayesian Statistics: Applications to Earthquake Engineering, Fig. 10 Fragility curves (mean) $Pf(PSa)$ and 95 % confidence intervals (CIs) for (a) $n = 10$ and (b) $n = 50$ records

and $y_{cr} = 2$, for two sets of $n = 10$ and $n = 50$ ground motion records, respectively. The ground motion samples used in the fragility analysis were simulated as zero-mean, nonstationary Gaussian processes with probability density functions $g_j(v)$ from the specific barrier model in Halldorsson and Papageorgiou (2005). Samples are generated for various (m, r) , according to the seismic activity matrix of Los Angeles. Fragility curves are constructed for both PGA and PSa intensity measures.

Figures 7 and 9 show the posterior distributions of the unknown parameters $\Theta = (\mu_{PGA}, \sigma_{PGA})$ and $\Theta = (\mu_{PSa}, \sigma_{PSa})$, which define the fragility curves for the PGA and PSa intensity measures, respectively. Plots (a) and (c) of each figure show the posterior of Θ obtained for $n = 10$ records and (b) and (d) for $n = 50$ records, respectively. Fragility curves for PGA and their corresponding 90 % confidence intervals calculated based on the posterior densities of Θ shown in Fig. 7a and c are illustrated in Fig. 8a and b, respectively. Fragility curves and their 90 % confidence intervals for the PSa intensity measure are plotted in Fig. 10 for the $n = 10$ and $n = 50$ ground motion sample sets. The posterior densities are less spread on the domain of Θ as the number of samples n increases. Consequently, the more data is used in the analysis, the narrower the confidence intervals for the fragility curves are.

Summary

The Bayesian framework, widely used in earthquake engineering, produces statistical inferences about uncertain parameters of a probabilistic model by combining observable data with available prior information about the parameters. The entry presents applications of Bayes' theorem for several concepts used in earthquake engineering.

The data is usually composed of ground motion records, which are used to develop probabilistic parametric models for fragility curves or to improve and update existent models on earthquake probabilities and frequency content of seismic motions. The Bayesian framework also facilitates the calculations of various statistics by using limited amounts of data.

Beginner's Guide to Fragility, Vulnerability, and Risk

Keith Porter

Civil, Environmental, and Architectural Engineering, University of Colorado, Boulder and SPA Risk LLC, Denver, CO, USA

Introduction

This entry provides a primer for earthquake-related fragility, vulnerability, and risk. Many of its concepts can be applied to other perils. Section “**Fragility**” discusses fragility – the probability of an undesirable outcome as a function of excitation. Vulnerability (the measure of loss as a function of excitation) is discussed in section “**Vulnerability**.” Section “**Hazard**” presents enough information about seismic hazard for the reader to understand risk, which is discussed in section “**Risk for a Single Asset**.” Section “**Conclusions**” provides brief conclusions. For solved exercises, see Porter (2014).

Fragility

Uncertain Values

Many of the terms used here involve uncertain quantities, often called random variables. “Uncertain” is used here because it applies to quantities that change unpredictably (e.g., whether a tossed coin will land heads or tails side up on the next toss) and to quantities that do not vary but that are not known with certainty. For example, a particular building’s capacity to resist collapse in an earthquake may not vary much over time, but one does not know that capacity before the building collapses, so it is uncertain. In this entry, uncertain variables are denoted by capital letters, e.g., D ; particular values are denoted by lower case, e.g., d ; probability is denoted by $P[\]$; and conditional probability is denoted by $P[A|B]$, that is, probability that statement A is true given that statement B is true.

Meaning and Form of a Fragility Function

The stage is now set to discuss fragility functions. A fragility function expresses the probability that an undesirable event will occur as a function of the value of some (potentially uncertain) environmental excitation. Let X denote the excitation. A fragility function is usually shown on an x - y chart with probability on the y -axis (bounded by 0 and 1) and excitation X on the x -axis (usually bounded below by 0 and above by infinity). (The variable X is used more than once in this entry. It may have different meanings in different places.)

When the undesirable outcome has to do with damage to a whole building, bridge, or other large facilities, excitation is generally measured in terms of ground motion. Common measures of ground motion are addressed later. When the undesirable outcome has to do with damage to a building component, excitation is often measured in terms of one of the following:

Peak floor acceleration (PFA). Maximum zero-period acceleration in any direction at any time during an earthquake at the base of floor-mounted components or at the soffit of

the slab from which a component is suspended.

Peak floor velocity (PFV). Like PFA, except maximum velocity at the base of the floor-mounted components or at the soffit of the slab from which a component is suspended.

Peak transient interstory drift ratio (PTD). This is the maximum value at any time during seismic excitation of the displacement of the floor above relative to the floor below the story on which a component is installed, divided by the height difference of the two stories. The displacements are commonly measured parallel to a horizontal axis of the component, such as along a column line.

Peak residual drift ratio (PRD). Like PTD, except measures the displacement of the floor above relative to the floor below after the cessation of motion.

Some people use the term fragility curve to mean the same thing as fragility function. Some use fragility and vulnerability interchangeably. This work will not do so and will not use the expression “fragility curve” or “vulnerability curve” at all. A function allows for a relationship between loss and one, two, or more inputs, whereas a curve only allows for one input.

The most common form of a seismic fragility function is the lognormal cumulative distribution function (CDF). It is of the form

$$\begin{aligned} F_d(x) &= P[D \geq d | X = x] \quad d \in \{1, 2, \dots, n_D\} \\ &= \Phi\left(\frac{\ln(x/\theta_d)}{\beta_d}\right) \end{aligned} \quad (1)$$

$P[A/B]$ = probability that A is true given that B is true.

D = uncertain damage state of a particular asset such as a building component or a building. It can take on a value in $\{0, 1, \dots, n_D\}$, where $D = 0$ denotes the undamaged state, $D = 1$ denotes the first damage state, etc.

d = a particular value of D , i.e., with no uncertainty.

n_D = number of possible damage states, $n_D \in \{1, 2, \dots\}$.

X = uncertain excitation, e.g., peak zero-period acceleration at the base of the asset in question. Here excitation is called demand parameter (DP), using the terminology of FEMA P-58 (Applied Technology Council 2012). FEMA P-58 builds upon work coordinated by the Pacific Earthquake Engineering Research (PEER) Center and others. PEER researchers use the term engineering demand parameter (EDP) to mean the same thing. Usually $X \in \{\Re \geq 0\}$ but it does not have to be. Note that $X \in \{\Re \geq 0\}$ means that X is a real, nonnegative number.

x = a particular value of X , i.e., with no uncertainty.

$F_d(x)$ = a fragility function for damage state d evaluated at x .

$\Phi(s)$ = standard normal cumulative distribution function (often called the Gaussian) evaluated at s , e.g., `normsdist(s)` in Excel.

$\ln(s)$ = natural logarithm of s .

θ_d = median capacity of the asset to resist damage state d measured in terms of X . Usually $\theta_d \in \{\Re > 0\}$ but it could in principle have a vector value and perhaps negative values. The subscript d appears because a component can sometimes have $n_D > 1$.

β_d = logarithmic standard deviation of the uncertain capacity of the asset to resist damage state d .

For example, see the PACT fragility database at https://www.atcouncil.org/files/FEMAP-58-3_2_ProvidedFragilityData.zip (Applied Technology Council 2012). See the tab PERFORMANCE DATA, the line marked C3011.002c. It employs the lognormal form to propose two fragility functions for Wall Partition, Type: Gypsum + Ceramic Tile, Full Height, Fixed Below, Slip Track Above w/ returns (friction connection). The demand parameter is "Story Drift Ratio," meaning the time-maximum absolute value of the peak transient drift ratio for the story at which partition occurs. For that component, $n_D = 2$, which occur sequentially, meaning that a component must enter damage state

1 before it can enter damage state 2. Damage state 1 is defined as "minor cracked joints and tile." Damage state 2 is defined as "cracked joints and tile." $\theta_1 = 0.0020$, $\beta_1 = 0.70$, $\theta_2 = 0.0050$, and $\beta_2 = 0.40$. The repair for $D = 1$ is described as "carefully remove cracked tile and grout at cracked joints, install new ceramic tile and re-grout joints for 10 % of full 100 foot length of wall. Existing wall board will remain in place." Repair for $D = 2$ is "install ceramic tile and grout all joints for full 100 foot length of wall. Note: gypsum wall board will also be removed and replaced which means the removal of ceramic tile will be part of the gypsum wall board removal."

The Lognormal Distribution

The lognormal is ubiquitous in probabilistic seismic hazard analysis (PSHA) and probabilistic seismic risk analysis (PSRA). To understand it, consider first the normal (*not* the lognormal) distribution. If a quantity X is normally distributed with mean μ and standard deviation σ , it can take on any scalar value in $-\infty < X < \infty$. Its cumulative distribution function (CDF) can be expressed as follows:

$$P[X \leq x] = \Phi\left(\frac{x - \mu}{\sigma}\right) \quad (2)$$

Note that:

$\mu \in \{\Re\}$, meaning that μ is any real scalar value
 $\sigma \in \{\Re > 0\}$, meaning that σ is any positive scalar value.

One can also find the value x associated with a specified nonexceedance probability, p .

$$x = \mu + \sigma \cdot \Phi^{-1}(p) \quad (3)$$

Now consider to the lognormal distribution. If a variable is lognormally distributed, that means its natural logarithm is normally distributed, which means it must take on a positive real value and the probability of it being zero or negative is zero. One can write the CDF several different, equivalent, ways:

$$\begin{aligned}
 P[X \leq x] &= \Phi\left(\frac{\ln x - \ln \theta}{\beta}\right) \\
 &= \Phi\left(\frac{\ln(x/\theta)}{\beta}\right) \\
 &= \Phi\left(\frac{\ln x - \mu_{\ln X}}{\sigma_{\ln X}}\right)
 \end{aligned} \tag{4}$$

where $\mu_{\ln X}$ denotes the mean value of $\ln(X)$, which is the same as the natural logarithm of the median, $\ln(\theta)$. It is sometimes desirable to calculate θ and β in terms of μ and σ . Here are the conversion equations. (The reader can learn more about probability distributions from various sources, such as the free online source NIST/SEMATECH (2013) or Ang and Tang (1975).) Let v denote the coefficient of variation of X . Then

$$v = \frac{\sigma}{\mu} \tag{5}$$

$$\beta = \sqrt{\ln(1 + v^2)} \tag{6}$$

$$\theta = \frac{m}{\sqrt{1 + v^2}} \tag{7}$$

Note well: there is nothing fundamental about the lognormal distribution that makes it ideal or exact for fragility functions, ground motion, and so on. It is commonly used for several reasons:

1. Simplicity. It only requires two parameter values to completely define.
2. Precedent. The lognormal has been used for fragility functions for decades.
3. Information-theory reasons. Given a median and logarithmic standard deviation of some uncertain positively valued quantity like component capacity, the lognormal is the most uncertain distribution, that is, it assumes the least amount of information.
4. Sometimes it fits the data well.

But the lognormal may fit data badly, sometimes worse than other competing parametric and nonparametric forms. Beware oversimplification,

and never confuse a mathematical simplification or model with reality. Ideally one's model approximates reality, but the model is not the thing itself.

Multiple Fragility Functions

Consider situations where a component, asset, or person can experience multiple possible damage states. This entry considers only discrete damage states, meaning that one can number the damage states $D = 1, 2$, etc., but not 1.5. If a component is damaged, one can number damage states in at least one of three ways. First, let $D = 0$ denote the undamaged state. If the component or asset is damaged, let the damage state be denoted by $D \in \{1, 2, \dots, n_D\}$. The three kinds of fragility functions dealt with here are:

1. Sequential damage states. A component must enter damage state 1 before it can enter damage state 2, and it must enter 2 before 3, and so on.
2. Simultaneous damage states. A damaged component can be in more than one damage state at the same time. Order does not matter.
3. Mutually exclusive and collectively exhaustive (MECE) damage states. A damaged component can be in one and only one damage state. Order does not matter.

There are other ways to express fragility, such as with a vector that combines numbers of various types. For example, one might want to talk about a scalar quantity Q of a component that is in a particular sequential damage state D , such as the fraction of a reinforced concrete shear wall that has cracks of at least 3/8 in. width, which would be indicative of the quantity of steel that has to be replaced. But the present discussion is limited to the three kinds noted above.

Sequential Damage States

In sequential damage states, the damage states are ordered (D is therefore an ordinal number, subject to certain mathematical rules of ordinal numbers), so one can talk about lower damage states

and higher ones. The probability of reaching or exceeding a lower damage state is greater than or

equal to the probability of reaching or exceeding a higher damage state.

$$\begin{aligned}
 P[D = d|X = x] &= 1 - P[D \geq 1|X = x] & d = 0 \\
 &= P[D \geq d|X = x] - P[D \geq d + 1|X = x] & 1 \leq d < n_D \\
 &= P[D \geq d|X = x] & d = n_D
 \end{aligned} \tag{8}$$

The first line is the probability that the component is undamaged. The next is the probability that the component is damaged, but not in damage state n_D , called the maximum damage state. The last line is the probability that the component is damaged in the maximum damage state.

Simultaneous Damage States

With simultaneous damage states, one can evaluate the probability that a component is in each damage state independently of the others. Because order does not matter, damage states D are nominal numbers, like the numbers on football jerseys without any order, although $D = 0$ is reserved for the undamaged state.

$$\begin{aligned}
 P[D = d|X = x] &= 1 - P[D \geq 1|X = x] & d = 0 \\
 &= P[D \geq 1|X = x] \cdot P[D = d|D \geq 1] & 1 \leq d \leq n_D
 \end{aligned} \tag{9}$$

where

$P[D \geq 1|X = x]$ = probability that the component is damaged in some way, which can be quantified just like any fragility function, such as with a lognormal CDF:

$$P[D \geq 1|X = x] = \Phi\left(\frac{\ln(x/\theta)}{\beta}\right) \tag{10}$$

where there are only one value of θ and only one value of β – no subscripts as in Eq. 1 – that is, a single median and logarithmic standard deviation of capacity. Note that the fragility function does not have to be a lognormal CDF, but that is common.

$P[D = d|D \geq 1]$ = probability that, if damaged, it is in damage state d . It can be in others as well.

Since under simultaneous damage states a component can be in more than one damage state,

$$\left(\sum_{d=1}^{n_D} P[D = d|D \geq 1]\right) > 1 \tag{11}$$

How can one estimate the probability that a component is in one and only one damage state? Let d_i denote one particular value of D and d_j another particular value of D , but $d_i \neq d_j$, $d_i \neq 0$, and $d_j \neq 0$. Let $P[D = d_i \& D \neq d_j|X = x]$ denote the probability that the component is in damage state d_i and it is not in any other damage state d_j given that $X = x$. It is given by

$$\begin{aligned}
 P[D = d_i \& D \neq d_j|X = x] &= P[D \geq 1, D = d_i|X = x] \cdot \prod_j (1 - P[D = d_j|D \geq 1, X = x]) \\
 &= P[D \geq 1|X = x] \cdot P[D = d_i|D \geq 1, X = x] \cdot \prod_j (1 - P[D = d_j|D \geq 1, X = x]) \\
 &= P[D \geq 1|X = x] \cdot P[D = d_i|D \geq 1] \cdot \prod_j (1 - P[D = d_j|D \geq 1])
 \end{aligned} \tag{12}$$

Consider now the probability that the component is in exactly two damage states. Let D_1 denote the first of two nonzero damage states that the component is in and D_2 the second. Let $P[D_1 = d_i \& D_2 = d_j \& D \neq d_k | X = x]$ denote the probability

that the component is in two damage states $D_1 = d_i$ and $D_2 = d_j$ but not any other damage state d_k ($k \neq i, k \neq j, i \neq j, i \neq 0, j \neq 0$, and $k \neq 0$) given $X = x$. It is given by

$$\begin{aligned} P[D_1 = d_i \& D_2 = d_j \& D = d_k | X = x] \\ = P[D \geq 1 | X = x] \cdot P[D = d_i | D \geq 1] \cdot P[D = d_j | D \geq 1] \cdot \prod_k (1 - P[D = d_k | D \geq 1]) \end{aligned} \quad (13)$$

One could repeat for three damage states i, j , and k by repeating the pattern. It is the product of the probabilities that the component is in each damage state i, j , and k and the probabilities that it is not in each remaining damage state l, m, n , etc.

MECE Damage States

Remember that MECE means that, if the component is damaged (denoted by $D \geq 1$), it is in one and only one nonzero damage state. One can evaluate it by

$$\begin{aligned} P[D = d | X = x] &= 1 - P[D \geq 1 | X = x] & d = 0 \\ &= P[D \geq 1 | X = x] \cdot P[D = d | D \geq 1] & d \in \{1, 2, \dots, N_D\} \end{aligned} \quad (14)$$

$P[D \geq 1 | X = x]$ = probability that the component is damaged in some way, which one evaluates with a single fragility function. If the fragility function is taken as a lognormal CDF, see Eq. 10. Note that the fragility function does not have to be a lognormal CDF, but that is common.

$P[D = d | D \geq 1]$ = probability that, if damaged, it is damaged in damage state d (and not any other value of D). Since under MECE damage states a component can only be in one damage state,

$$\left(\sum_{d=1}^{N_D} P[D = d | D \geq 1] \right) = 1 \quad (15)$$

Creating Fragility Functions

What to Know Before Trying to Derive a Fragility Function

Consider now how fragility functions are made. Much of this section is drawn from Porter et al. (2007). Before trying to derive a fragility

function, the analyst should define failure in unambiguous terms that do not require the exercise of judgment, i.e., where two people observing the same specimen would reach the same conclusion as to whether a specimen has failed or not. Beware damage scales that do not meet this test. Second, define the excitation to which specimens are subjected (maximum base acceleration, peak transient drift ratio, etc.) in similarly unambiguous terms. Third, select specimens without bias with respect to failure or nonfailure. That is, one cannot use data about specimens that were observed *because* they were damaged or because the damage was prominent or interesting in some way. (Failure data gathered by reconnaissance surveys tend to be biased in this way.) Fourth, ensure that specimens were subjected to multiple levels of excitation.

Actual Failure Excitation

In the unusual case where specimens were all tested in a laboratory to failure and the actual excitation at which each specimen failed is known, then one can fit a lognormal fragility

function to the data as follows. This kind of data is referred to here as type A data, A for actual failure excitation. Before using the following math, the analyst must clearly define “failure” and should know both the means of observing specimen excitation and failure, as well as a clear definition of the component or other asset category in question:

n_i = number of specimens, $n_i \geq 2$.
 i = index to specimens, $i \in \{1, 2, \dots, n_i\}$.
 r_i = excitation at which specimen i failed.

$$\theta = \frac{1}{n_i} \sum_{i=1}^{n_i} \ln(r_i) \quad (16)$$

$$\beta = \sqrt{\frac{1}{n_i - 1} \sum_{i=1}^{n_i} (\ln(r_i/\theta))^2} \quad (17)$$

Bounding-Failure Excitation

Suppose one possesses observations where at least one specimen did not fail, at least one specimen did fail, and one knows the peak excitation to which each specimen was subjected, but not the actual excitation at which each specimen failed. These data are referred to here as bounding, or type B, data. Specimens are grouped by the maximum level of excitation to which each specimen was subjected. Assume the fragility function is reasonably like a lognormal cumulative distribution function and find the parameter values θ (median) and β (logarithmic standard deviation) as follows:

m_i = numbers of levels of excitation among the data, referred to here as bins, $m_i \geq 2$.
 i = bin index, $i \in \{1, 2, \dots, m_i\}$.
 r_i = maximum excitation to which specimens in bin i were subjected.
 n_i = number of specimens in bin i , $n_i \in \{1, 2, \dots\}$.
 f_i = number of specimens in bin i that failed, $f_i \in \{0, 1, \dots, n_i\}$.

One proper way to estimate θ and β is by the maximum likelihood method, i.e., by finding the

values of θ and β that have the highest likelihood of producing the observed data. At any level of excitation r_i , there is a probability of any individual specimen failing that is given by the lognormal CDF. Let p_i denote this probability:

$$p_i = \Phi\left(\frac{\ln(r_i/\theta)}{\beta}\right) \quad (18)$$

Assume that the failure of any two different specimens is independent conditioned on excitation. In that case, if one were to estimate the number of failed specimens in bin i , it would be proper to take that number as a random variable with a binomial distribution. Let F_i denote that random variable. The following equation gives the probability that one will observe f_i failures among n_i specimens with the per-occurrence failure probability p_i :

$$P[F_i = f_i] = \frac{n_i!}{f_i!(n_i - f_i)!} \cdot p_i^{f_i} \cdot (1 - p_i)^{n_i - f_i} \quad (19)$$

This is the binomial distribution. One finds the θ and β values that maximize the likelihood of observing all the data $\{n_1, f_1, n_2, f_2, \dots\}$ given excitations $\{r_1, r_2, \dots\}$. That likelihood is given by the product of the probabilities in Eq. 19, multiplied over all the bins. That is, find θ and β that maximize $L(\theta, \beta)$ in:

$$L(\theta, \beta) = \prod_{i=1}^{m_i} P[F_i = f_i] \quad (20)$$

One can explicitly maximize $L(\theta, \beta)$, but it is easier to use Excel or similar MATLAB or other software. Excel's solver is straightforward.

It may be easier to remember a more approximate approach of minimizing the weighted squares of the difference between the observed data and the idealized fragility function. That is, find θ and β that minimize the squared error term $\varepsilon^2(\theta, \beta)$ in:

$$\varepsilon^2(\theta, \beta) = \sum_{i=1}^{m_i} n_i \cdot \left(p_i - \frac{f_i}{n_i}\right)^2 \quad (21)$$

The difference between the fragility functions derived by these two different methods generally appears to be small compared with the scatter about the regression lines, so arguments about what is more proper tend to be academic compared with the choice of which one is easier. There is at least one more reasonable approach, called logistic regression, but again this approach tends to produce roughly the same values of θ and β , with differences that are small compared with data scatter.

Other Data Conditions

There are cases where none of the specimens failed (type C, or capable, data), where failure is derived by structural analysis (type D data), where expert opinion is used (type E), or where Bayesian updating is used to update an existing fragility function with new evidence (type U). For such situations, see Porter et al. (2007).

Dealing with Under-Representative Specimens

If the specimens used to create the fragility function are very few in number or unrepresentative of the broader class whose fragility is desired, or if the excitation to which they were subjected was unlike real-world earthquake shaking, one can reflect added uncertainty associated with unrepresentative conditions by increasing the fragility function's logarithmic standard deviation. The FEMA P-58 guidelines, for example, suggest always increasing the logarithmic standard deviation of a fragility function that is derived from test data or observations, as follows:

$$\beta' = \sqrt{\beta^2 + \beta_u^2} \quad (22)$$

where β' is the new, increased value of the logarithmic standard deviation of the fragility function, β is the value derived using the test or post-earthquake observation data, and β_u is a term to reflect uncertainty that the tests represent real-world conditions of installation and loading or uncertainty that the available data are an adequate sample size to accurately represent the true variability.

FEMA P-58 recommends values of β_u depending on how under-representative are the

data. If any of the following is true, use a minimum value of $\beta_u = 0.25$; otherwise, use $\beta_u = 0.10$.

1. Data are available for five or fewer specimens.
2. In an actual building, a component can be installed in a number of different configurations, but all specimens were tested with the same configuration.
3. All specimens were subjected to the same loading protocol.
4. Actual behavior of the component is expected to be dependent on two or more demand parameters (e.g., simultaneous drift in two orthogonal directions), but specimens were loaded using only one demand parameter.

In the case of type B data, increasing β using Eq. 22 introduces a bias in long-term failure probability and can cause the fragility function not to pass through the actual failure data well. If the data generally lie at excitation levels below the derived median capacity θ , which is common, then increasing β without adjusting θ will cause the fragility function to move up (to higher probabilities) relative to the data. To increase β while still ensuring that the derived fragility function passes through the data, one can adjust θ as follows:

$$\bar{r} = \frac{\sum_{i=1}^{N_i} r_i \cdot n_i}{\sum_{i=1}^{N_i} n_i} \quad (23)$$

$$\theta' = \bar{r} \cdot \left(\frac{\bar{r}}{\theta} \right)^{(-\beta'/\beta)} \quad (24)$$

In the case of type A data, use $n_i = 1$ for all i in Eq. 23. For example, imagine that 17 suspended ceilings of identical construction are installed in a large, stiff single-story building, a block away from a 2-story building with three suspended ceilings on the upper floor. A ceiling in the 1-story building and two ceilings in the 2-story building collapse in a particular earthquake. The estimated roof accelerations in the two buildings are 0.25 and 0.45 g, respectively. These type

Beginner's Guide to Fragility, Vulnerability, and Risk, Fig. 1 Increasing beta and adjusting theta to account for under-representative samples

B data are used to derive a fragility function in terms of peak floor acceleration, with $\beta = 0.3$ and $\theta = 0.4$ g. These conditions meet FEMA P-58's criteria 2 and 3, so $\beta_u = 0.25$. Applying the FEMA P-58-recommended value $\beta_u = 0.25$ and evaluating Eqs. 22, 23, and 24 yields

$$\begin{aligned}\beta' &= \sqrt{0.3^2 + 0.25^2} = 0.39 \\ \bar{r} &= \frac{(17 \cdot 0.25 + 3 \cdot 0.45)}{20} = 0.28 \\ \theta' &= 0.28 \cdot \left(\frac{0.28}{0.4}\right)^{(-0.39/0.30)} = 0.45\end{aligned}$$

Figure 1 illustrates the data, the fragility function before increasing β (the solid line) and the fragility function after increasing β . Note how the two curves cross at $r = \bar{r}$ and how $\theta' > \theta$. The solid curve passes through the data because there are only two data points, but it passes over the first data point and below the second, closer to the first because the first represents more data.

Some Useful Sources of Component Fragility Functions

FEMA P-58 produced a large suite of component fragility functions. See https://www.atcouncil.org/files/FEMAP-58-3_2_ProvidedFragilityData.zip.

“Component” means a building component, like an RSMeans assembly such as glass curtain walls. The component fragility functions in FEMA P-58 mostly use as excitation measures the peak transient interstory drift ratio to which a drift-sensitive specimen is subjected or the peak absolute acceleration of the floor or roof to which the specimen is attached, for acceleration-sensitive components. In some cases peak residual drift is used (e.g., doors getting jammed shut). There are other measures of excitation as well. FEMA P-58 failure modes are defined with symptoms of physical damage or nonfunctionality requiring particular, predefined repair measures. They are never vague qualitative states such as “minor damage” that require judgment to interpret. Most of the FEMA P-58 fragility functions are derived from post-earthquake observations or laboratory experiments. Some are based on structural analysis and some are derived from expert opinion. All were peer reviewed. Johnson et al. (1999) also offer a large library of component fragility functions, many based on post-earthquake observations of standard mechanical, electrical, and plumbing equipment in power facilities.

The HAZUS-MH technical manual (NIBS and FEMA 2009) offers a number of whole-building fragility functions, defining for instance probabilistic damage to all the drift-sensitive nonstructural components in the building in four qualitative damage states (slight, moderate, extensive, complete) as a function of a whole-building measure of structural response (spectral acceleration response or spectral displacement response of the equivalent nonlinear SDOF oscillator that represents the whole building).

Vulnerability

Vulnerability Terminology

So far, this entry has discussed damageability in terms of the occurrence of some undesirable event such as a building collapse that either occurs or does not occur. Damageability is also measured in terms of the degree of the

undesirable outcome, called loss here, in terms of repair costs, life-safety impacts, and loss of functionality (dollars, deaths, and downtime) or in terms of environmental degradation, quality of life, historical value, and other measures. When loss is depicted as a function of environmental excitation, the function can be called a vulnerability function. A seismic vulnerability function relates uncertain loss to a measure of seismic excitation, such as spectral acceleration response at some damping ratio and period. A seismic vulnerability function usually applies to a particular asset class.

Vulnerability is not fragility. Vulnerability measures loss; fragility measures probability. Vulnerability functions are referred to many ways: damage functions, loss functions, vulnerability curves, and probably others.

When a vulnerability function measures repair cost, it is commonly normalized by replacement cost new (RCN), a term which here means the cost of a similar new property having the nearest equivalent utility as the property being appraised, as of a specific date (American Society of Appraisers 2013). RCN excludes land value and usually refers to part or all of the fixed components of a building or other assets (structural, architectural, mechanical, electrical, and plumbing components) or to its contents. Repair cost divided by RCN is referred to here as damage factor (DF). Some authors call it damage ratio, fractional loss, or other terms. The expected value of DF conditioned on excitation is commonly called mean damage factor (MDF). Sometimes it is assumed that if DF exceeds some threshold value such as 0.6, the property is not worth repairing and is a total loss, so repair-cost vulnerability functions can jump abruptly from 0.6 (or other threshold value) to 1.0 with increasing excitation. In principle DF can exceed 1.0 because it can cost more to repair a building than to replace it.

When a vulnerability function measures life-safety impacts, it commonly measures the fraction of indoor occupants who become casualties (that is, they are killed or experience a nonfatal injury to some specified degree) as a function of excitation. There are a variety of human-injury

scales, some used by civil engineers and others used by public health professionals. Before using a terms such as minor injury, one should be sure its meaning is entirely clear and meaningful to the intended user of the vulnerability information. Civil engineers sometimes use casualty scales that are ambiguous or not useful to public health professionals.

Downtime is commonly measured in terms of days or fractions of a year during which the asset cannot be used for its intended purposes. Sometimes it measures the time from the environmental shock (the earthquake, in the case of a seismic vulnerability function) to the time when all repairs are completed, which includes both the time required to perform the repairs and a previous period during which damage is assessed, repairs are designed, financing is arranged, repairs are bid out, and the repair contractor mobilizes to the site.

Many vulnerability functions are expressed with conditional probability distributions that give a probability that loss will not exceed some specified value given the excitation, for a particular asset class. The distribution is often assigned a parametric form such as lognormal or beta, in which case the parameters of the distribution are all required, some or all of them conditioned on excitation. Figure 2 presents a sample probabilistic vulnerability function.

Brief Summary of Vulnerability Derivation Methods

While this entry does not provide guidance on how to derive vulnerability functions, it is worthwhile to understand the different approaches to doing so and some of the relevant history. There are three distinct approaches – sometimes referred to as empirical, analytical, and expert opinion – and some hybrids that combine aspects of two or more approaches. They are briefly explained here.

An empirical vulnerability function is one derived by regression analysis of observations of pairs of excitation and loss for specimens of an asset class. Professional users of vulnerability functions such as insurance loss estimators tend to prefer empirical vulnerability functions over

Beginner's Guide to Fragility, Vulnerability, and Risk, Fig. 2 Sample vulnerability function that relates damage factor to 1-s spectral acceleration response for some asset class. The *solid line* depicts the expected value of damage factor, and the *dotted curve* depicts the probability density function of damage factor at 1 g of excitation

other approaches, because they are known to be based on real-world observations. One of the best examples of an empirical vulnerability function is the one derived by Wesson et al. (2004), who performed regression analysis of losses to single-family housing from ground motion in the 1994 Northridge earthquake. Among the challenges to deriving empirical vulnerability functions are the scarcity of nearby ground motion observations, the difficulty getting reliable loss information, and relatively few observations at high levels of ground motion.

Analytical methods are useful when empirical data are lacking and one has the time and other resources to create and analyze a model. An analytical approach generally involves defining one or more specimens to represent the class, creating and analyzing a structural model to estimate structural response as a function of ground motion, estimating component-level damage given structural response, and then estimating loss given component damage. The interested reader is referred to FEMA P-58 (ATC 2012) for the current state of the practice for individual buildings and to Porter et al. (2009a, b; 2010,

2014) for building classes. Analytical methods offer the advantage of being able to distinguish the effect of any feature of interest and any asset class the analyst can model, but the disadvantages of cost and often a lack of data to validate the results.

Expert opinion can quickly provide vulnerability functions where empirical data are missing and the analyst lacks the resources for an analytical model. Briefly, one convenes a group of experts familiar with the performance of the asset class of interest and with a structured interview process elicits their judgment of the performance of the class at each of many levels of excitation. ATC-13 (1985) represents one of the earliest and most thorough expert-opinion models of the seismic vulnerability of buildings and other asset classes. Jaiswal et al. (2012) offers a more recent example.

Hazard

Probabilistic Seismic Hazard Analysis

Seismic hazard refers here to an uncertain relationship between the level of some measure of seismic excitation and the frequency or probability of a particular location experiencing at least that level of excitation. It is *not* the measure of excitation, the occurrence of an earthquake, nor the probability or frequency of excitation. These terms are not to be used interchangeably.

Seismic hazard is quantified many ways. One is through a hazard curve, commonly depicted on an x - y chart where the x -axis measures shaking intensity at a site and the y -axis measures either exceedance probability in a specified period of time or exceedance rate in events per unit time. See Fig. 3 for an example Cornell (1968) applied the theorem of total probability to create a hazard curve. What follows here is a summary of current procedures to perform probabilistic seismic hazard analysis (PSHA), but is conceptually identical to Cornell's work.

Engineers sometimes refer to the quantity by which intensity is measured as the intensity measure. Earth scientists call it ground motion. The present work uses the term intensity measure (IM).

Beginner's Guide to Fragility, Vulnerability, and Risk, Fig. 3 Sample hazard curve. The *solid line* shows the mean rate at which various levels of 1 s spectral acceleration response are exceeded. The *dotted line* shows that 0.5 g is exceeded on average about once in 600 years

Some authors distinguish between the intensity measure type (IMT), such as 5 % damped spectral acceleration response at 0.2 s period, and the intensity measure level (IML), a particular value of the IM such as 0.4 g. In any case, IMT must be completely specified. If using damped elastic spectral acceleration response, one states the period, damping ratio, and whether one is referring to the geometric mean of two orthogonal directions or the maximum direction or other directional references.

To estimate seismic hazard, one applies the theorem of total probability to combine the uncertain shaking at the site caused by a particular fault rupture and the occurrence frequency or probability of that rupture. Earth scientists create models called earthquake rupture forecasts that specify the locations and rates at which various fault produce earthquakes of various sizes, e.g., the Uniform California Earthquake Rupture Forecast version 2 (UCERF2, Field et al. 2007). The uncertain shaking given a fault rupture is quantified using a relationship variously called an attenuation relationship or a ground-motion prediction equation, such as the next-generation attenuation (NGA) relationships presented in the

February 2008 issue of *Earthquake Spectra*. Mathematically, a hazard curve is created as follows. Let:

H = uncertain severity of ground motion at the building site, e.g., $S_a(T, 5\%)$.

h = a particular value of H .

$G(h)$ = frequency (events per unit time) with which $H > h$, i.e., the number of events per unit time in which at least once during the event, $H > h$.

n_E = number of earthquake rupture forecast models to consider, $n_E \in \{1, 2, \dots\}$. For example, in UCERF2, there were 480 discrete combinations of fault model, rupture model, magnitude-area relationship, and several other modeling choices that together are represented by a logic tree that begins with fault model, branches to rupture model, then to magnitude-area relationship, etc. For UCERF2, $n_E = 480$.

E = the “correct” earthquake rupture forecast, which is uncertain. $E \in \{1, 2, \dots, n_E\}$.

e = an index to a particular earthquake rupture forecast, $e \in \{1, 2, \dots, n_E\}$.

$P[E = e]$ = Bayesian probability assigned to earthquake rupture forecast e . In UCERF2, this would be the product of the conditional probabilities (weights) of the individual branches in the logic tree that represents UCERF2. Conditional probability means that each branch’s probability can (though only sometimes do) depend on which choices came before it.

n_A = number of attenuation relationships (also called ground motion prediction equations) to be employed, $n_A \in \{1, 2, \dots\}$

A = the “correct” ground-motion-prediction equation, i.e., the one that expresses the true state of nature, which is uncertain.

a = an index to ground-motion prediction equations.

$P[A = a]$ = Bayesian probability assigned to ground-motion-prediction equation a , i.e., the probability that ground-motion-prediction equation a actually reflects the true state of nature and is therefore the correct ground-motion-prediction equation.

$n_F(e)$ = number of fault sections in earthquake rupture forecast e , $n_F(e) \in \{1, 2, \dots\}$.

f = an index to faults section, $f \in \{1, 2, \dots n_F(e)\}$.

m_0 = minimum magnitude to consider.

Δm = an increment of magnitude, say, $\Delta m = 0.1$.

$M_{\max}(f|E = e)$ = maximum magnitude of which fault f is deemed capable under earthquake rupture forecast e , $M_{\max}(f|E = e) \in \{m_0 + \frac{1}{2} \cdot \Delta m, m_0 + \frac{3}{2} \cdot \Delta m, \dots\}$.

$n_o(f, m)$ = number of locations within fault section f that can generate a rupture of magnitude m , $n_o(f, m) \in \{1, 2, \dots\}$.

o = an index to locations on fault section f , in $o \in \{1, 2, \dots n_o(f, m)\}$.

$G(f, m, o|E = e)$ = frequency (events per unit time) with which fault section f ruptures at location o producing earthquake of magnitude $m \pm \frac{1}{2} \cdot \Delta m$ given earthquake rupture forecast e .

V_S = uncertain site soil, potentially measured by NEHRP site soil classification or shearwave velocity in the top 30 m of soil (Vs30) or something else. To find Vs30, see the site data application at www.opensha.org/apps for U.S. locations or Google the USGS's Global Vs30 map server for other locations

v = a particular value of V .

$P[H > h | m, r, v, a]$ = probability that $H > h$ given earthquake magnitude m at distance r on soil with soil type v using ground-motion prediction equation a . Note that, given a known site location, fault segment f , and location along the fault segment o , distance r from the site to the fault is known. Note that ground-motion prediction equations use a variety of distance measures. As of this writing, most ground-motion prediction equations give an equation for the mean of the natural logarithm of H given m , r , and v , for the logarithmic standard deviation of H (i.e., the standard deviation of the natural logarithm of H), and assume a lognormal distribution of H conditioned on m , r , and v . Let $m_{\ln H}$ and $s_{\ln H}$ denote the mean of $\ln(H)$ and the standard deviation of $\ln(H)$, respectively, given m , r , and v , assuming ground-motion-prediction equation a . Under these conditions,

$$P[H > h | m, r, v, a] = 1 - \Phi\left(\frac{\ln(h) - m_{\ln H}}{s_{\ln H}}\right) \quad (25)$$

One can now estimate the hazard curve by applying the theorem of total probability. Suppose one always knew soil conditions V with certainty. Then

$$G(h) = \sum_{e=1}^{n_E} \sum_{a=1}^{n_A} \sum_{f=1}^{n_F(e)} \sum_{m} \sum_{o=1}^{n_o(f, m)} P[H > h | m, r, v, a] \cdot G(m, f, o | E = e) \cdot P[A = a] \cdot P[E = e] \quad (26)$$

where the summation over m means that one considers each $m \in \{m_0 + \frac{1}{2} \cdot \Delta m, m_0 + \frac{3}{2} \cdot \Delta m, \dots M_{\max}(f|E = e)\}$.

Hazard Rate Versus Probability

Seismic hazard is often expressed in terms of exceedance probability, rather than in terms of exceedance rate. The distinction is this: exceedance probability is the probability that shaking of $H > h$ will occur at least once in a given period of time. That means that it is the probability that it $H > h$ will occur exactly once, plus the probability that it will occur exactly twice, etc. For some calculations, the analyst wants rate (number of

events per unit time) not probability (chance that it occurs one or more times in a given time period).

The two can be related using a concept called a Poisson process. From the Wikipedia's article on the Poisson Process: "In probability theory, a Poisson process is a stochastic process which counts the number of events and the time that these events occur in a given time interval. The time between each pair of consecutive events has an exponential distribution with parameter G [the parameter is the occurrence rate per unit time] and each of these inter-arrival times is ... independent of other

inter-arrival times [meaning that the time between the second and third occurrence is independent of the time between the first and second occurrence – knowing one tells you nothing about the other, so a Poisson process is called memoryless]. The process is named after the French mathematician Siméon-Denis Poisson and is a good model of radioactive decay, telephone calls, and requests for a particular document on a web server, among many other phenomena.”

Modeling earthquakes as Poisson arrivals is convenient in part because in a Poisson process, arrival rate and occurrence probability have this relationship:

$$G = \frac{-\ln(1 - P)}{t} \quad (27)$$

where

G = occurrence rate, i.e., events per unit time,
 P = probability that at least one event will occur in time t .

So if a hazard curve were represented as $P(h)$, the probability that $H > h$ at least once in a particular period of time t , one could use Eq. 27 to estimate the occurrence rate $G(h)$, the average number of times that $H \geq h$ per unit time. One can also rearrange Eq. 27 to give probability as a function of rate:

$$P = 1 - e^{-G \cdot t} \quad (28)$$

So with the occurrence rate $G(h)$ of earthquakes causing $H > h$, one can calculate the probability that at least one earthquake with $H > h$ will occur in a given time t .

Measures of Seismic Excitation

These are many common measures of seismic excitation. Some measure ground motion and some measure structural response or excitation to which the components of a building, bridge, or other structural systems are subjected. This section introduces common ones.

Some Commonly Used Measures of Ground Motion

Peak ground acceleration (PGA). This is the maximum value of acceleration of a particular point on the ground at any time during an earthquake. Often PGA is estimated as the geometric mean (the square root of the product) of the maximum values of PGA parallel to each of two orthogonal horizontal axes. PGA is sometimes called zero-period acceleration (ZPA), meaning the spectral acceleration response of a single-degree-of-freedom elastic oscillator with zero, or near-zero, period. Before using a PGA value, be sure you know whether it refers to geometric mean, maximum-direction value, or something else.

Peak ground velocity (PGV). This is like PGA, except maximum velocity of a point on the ground rather than acceleration.

Peak ground displacement (PGD). This is like PGA, except maximum displacement relative to a fixed datum.

Spectral acceleration response ($S_a(T, z)$). This usually refers to damped elastic spectral acceleration response at some specified index period such as $T = 0.3$ s, 1.0 s, 3.0 s, etc., and specified damping ratio such as $z = 5\%$, at a particular point on the ground. To be precise, $S_a(T, z)$ is the absolute value of the maximum acceleration relative to a fixed datum of a damped elastic single-degree-of-freedom harmonic oscillator with period T and damping ratio z when subjected to a particular one-degree-of-freedom ground-motion time history at its base. In practice, it typically refers to the geometric mean of spectral acceleration response parallel to each of two orthogonal horizontal axes. It is so often measured for $z = 5\%$ that damping ratio is often not mentioned. Before using $S_a(T, z)$, be sure you know T , z , and whether it is a geometric mean value or the maximum-direction value or something else.

Spectral displacement response ($S_d(T, z)$). This is like $S_a(T, z)$ but for relative spectral displacement (displacement of the oscillator relative to its base, not relative to a fixed datum) rather than absolute acceleration of the oscillator.

Pseudoacceleration response ($PSA(T, z)$). $PSA(T, z)$ is defined as $S_d(T, z) \cdot \omega^2$, where ω is

angular frequency, $2 \cdot \pi/T$. Some authors prefer to use $PSA(T,z)$ rather than $S_a(T,z)$, but for values of z less than about 20 %, the two measures are virtually identical.

Modified Mercalli Intensity (MMI) and European Macroseismic Scale (EMS). These are macroseismic intensity measures, meaning that they measure seismic excitation over a large area, not at a particular point on the ground. They are measured with an integer scale in Roman numerals from I to XII. They measure whether and how people in a region such as a neighborhood or city felt and reacted to earthquake motion (did they run outside?) and what they observed to happen to the ground, buildings, and contents around them, such as plates rattling and weak masonry being damaged. They are subjective and generally easier for nontechnical audiences to understand than instrumental measures. On the MMI scale, building damage begins around MMI VI and it is rare for an earthquake to produce shaking of $MMI \geq X$. EMS is similar to MMI, but building-damage observations are related to common European building types. A version of EMS defined in 1998 is often referred to as EMS-98. For detail see Table 1, Wood and Neumann (1931) and European Seismic Commission Working Group—Macroseismic Scales (1998).

Japan Meteorological Agency (JMA) seismic intensity scale. This is like MMI, but with a 0–7 scale. It has both a macroseismic sense (observed effects of people and objects) and an instrumental sense (in terms of ranges of PGA). See http://en.wikipedia.org/wiki/Japan_Meteorological_Agency_seismic_intensity_scale for details.

Instrumental intensity measure (IMM). This is a positively valued measure of intensity that can take on fractional values, e.g., 6.4. This is an estimate of MMI using functions of instrumental ground-motion measures such as PGA and PGV.

Conversion Between Instrumental and Macroseismic Intensity

It is often desirable to convert between instrumental ground-motion measures such as PGA or PGV and macroseismic intensity

measures, especially MMI. One reason is that MMI observations can be made by people exposed to shaking or who make post-earthquake observations, whereas instrumental measures require an instrument.

Ground motion to intensity conversion equations (GMICE). These estimate macroseismic intensity as a function of instrumental measures of ground motion. There are several leading GMICEs. When selecting among them, try to match the region, magnitude range, and distance range closest to the conditions where the GMICE will be applied. More data for conditions like the ones in question are generally better than less data, all other things being equal. When considering building response, GMICEs that convert from $S_a(T,z)$ to macroseismic intensity are generally better than those that use PGA or PGV, which do not reflect anything building-specific. Two recent GMICEs for the United States are as follows:

As of this writing, Worden et al.'s (2012) relationships in Eqs. 29 and 30 seem to be the best choice for estimating MMI from ground motion and vice versa for California earthquakes. The reason is they employ a very large dataset of California (ground motion, MMI) observations. The dataset includes 2092 PGA-MMI observations and 2074 PGV-MMI observations from 1207 California earthquakes $M = 3.0\text{--}7.3$, $MMI = 2.0\text{--}8.6$, $R = 4\text{--}500$ km. It includes no observations from continental interior. It includes regressions for $S_a(0.3\text{ s}, 5\%)$, $S_a(1.0\text{ s}, 5\%)$, $S_a(3.0\text{ s}, 5\%)$, PGA, and PGV that operate in both directions, meaning that one can rearrange the relationships to estimate instrumental measures in terms of MMI, as well as MMI in terms of instrumental measures. The reason that the relationships are bidirectional is that Worden et al. (2012) used a total least-squares data modeling technique in which observational errors on both dependent and independent variables are taken into account. Equation 30 includes the option to account for the apparent effects of magnitude M and distance R . The columns for residual standard deviations show a modest reduction in uncertainty when accounting for M and R (Table 2).

Beginner's Guide to Fragility, Vulnerability, and Risk, Table 1 MMI and EMS-98 macroseismic intensity scales (abridged)

MMI	Brief description	EMS-98	Brief description
I. Instrumental	Generally not felt by people unless in favorable conditions	I. Not felt	Not felt by anyone
II. Weak	Felt only by a couple people that are sensitive, especially on the upper floors of buildings. Delicately suspended objects (including chandeliers) may swing slightly	II. Scarcely felt	Vibration is felt only by individual people at rest in houses, especially on upper floors of buildings
III. Slight	Felt quite noticeably by people indoors, especially on the upper floors of buildings. Standing automobiles may rock slightly. Vibration similar to the passing of a truck. Indoor objects may shake	III. Weak	The vibration is weak and is felt indoors by a few people. People at rest feel swaying or light trembling. Noticeable shaking of many objects
IV. Moderate	Felt indoors by many people, outdoors by few. Some awakened. Dishes, windows, and doors disturbed, and walls make cracking sounds. Chandeliers and indoor objects shake noticeably. Like a heavy truck striking building. Standing automobiles rock. Dishes and windows rattle	IV. Largely observed	The earthquake is felt indoors by many people and outdoors by few. A few people are awakened. The level of vibration is possibly frightening. Windows, doors, and dishes rattle. Hanging objects swing. No damage to buildings
V. Rather strong	Felt inside by most or all and outside. Dishes and windows may break. Vibrations like a train passing close. Possible slight damage to buildings. Liquids may spill out of glasses or open containers. None to a few people are frightened and run outdoors	V. Strong	Felt indoors by most, outdoors by many. Many sleeping people awake. A few run outdoors. China and glasses clatter. Top-heavy objects topple. Doors and windows swing
VI. Strong	Felt by everyone; many frightened and run outdoors, walk unsteadily. Windows, dishes, glassware broken; books fall off shelves; some heavy furniture moved or overturned; a few instances of fallen plaster. Damage slight to moderate to poorly designed buildings; all others receive none to slight damage	VI. Slightly damaging	Felt by everyone indoors and by many outdoors. Many people in buildings are frightened and run outdoors. Objects on walls fall. Slight damage to buildings; for example, fine cracks in plaster and small pieces of plaster fall
VII. Very strong	Difficult to stand. Furniture broken. Damage light in buildings of good design and construction; slight to moderate in ordinarily built structures; considerable damage in poorly built or badly designed structures; some chimneys broken or heavily damaged. Noticed by people driving automobiles	VII. Damaging	Most people are frightened and run outdoors. Furniture is shifted and many objects fall from shelves. Many buildings suffer slight to moderate damage. Cracks in walls; partial collapse of chimneys

(continued)

Beginner's Guide to Fragility, Vulnerability, and Risk, Table 1 (continued)

MMI	Brief description	EMS-98	Brief description
VIII. Destructive	Damage slight in structures of good design, considerable in normal buildings with possible partial collapse. Damage great in poorly built structures. Brick buildings moderately to extremely heavily damaged. Possible fall of chimneys, monuments, walls, etc. Heavy furniture moved	VIII. Heavily damaging	Furniture may be overturned. Many to most buildings suffer damage: chimneys fall; large cracks appear in walls and a few buildings may partially collapse. Can be noticed by people driving cars
IX. Violent	General panic. Damage slight to heavy in well-designed structures. Well-designed structures thrown out of plumb. Damage moderate to great in substantial buildings, with a possible partial collapse. Some buildings may be shifted off foundations. Walls can collapse	IX. Destructive	Monuments and columns fall or are twisted. Many ordinary buildings partially collapse and a few collapse completely. Windows shatter
X. Intense	Many well-built structures destroyed, collapsed, or moderately damaged. Most other structures destroyed or off foundation. Large landslides	X. Very destructive	Many buildings collapse. Cracks and landslides can be seen
XI. Extreme	Few if any structures remain standing. Numerous landslides, cracks, and deformation of the ground	XI. Devastating	Most buildings collapse
XII. Catastrophic	Total destruction. Objects thrown into the air. Landscape altered. Routes of rivers can change	XII. Completely devastating	All structures are destroyed. The ground changes

Beginner's Guide to Fragility, Vulnerability, and Risk, Table 3 Parameter values for Atkinson and Kaka (2007) GMICE for the United States

Y	c ₁	c ₂	c ₃	c ₄	c ₅	c ₆	c ₇	σ_{MMI}	
								Eq. 31	Eq. 32
PGA	4.37	1.32	3.54	3.03	0.47	−0.19	0.26	0.80	0.76
PGV	2.65	1.39	−1.91	4.09	−1.96	0.02	0.98	1.01	0.89
PSA(0.3 s)	2.40	1.36	−1.83	3.56	−0.11	−0.20	0.64	0.88	0.79
PSA(1.0 s)	3.23	1.18	0.57	2.95	1.92	−0.39	0.04	0.84	0.73
PSA(2.0 s)	3.72	1.29	1.99	3.00	2.24	−0.33	−0.31	0.86	0.72

$$\begin{aligned}
 \text{MMI} &= c_1 + c_2 \cdot \log_{10}(Y) & \log_{10}(Y) \leq t_1 & & \text{MMI} &= c_1 + c_2 \log_{10}(Y) & \text{MMI} \leq 5 \\
 &= c_3 + c_4 \cdot \log_{10}(Y) & \log_{10}(Y) > t_1 & & &= c_3 + c_4 \cdot \log_{10}(Y) & \text{MMI} > 5
 \end{aligned} \quad (29)$$

$$\begin{aligned}
 \text{MMI} &= c_1 + c_2 \cdot \log_{10}(Y) + c_5 + c_6 \cdot \log_{10}(R) \\
 &+ c_7 \cdot M & \text{MMI} \leq t_2 \\
 &= c_3 + c_4 \cdot \log_{10}(Y) + c_5 + c_6 \cdot \log_{10}(R) \\
 &+ c_7 \cdot M & \text{MMI} > t_2
 \end{aligned} \quad (30)$$

Units of Y are cm/s or cm/s, 5 % damping. Units of R are km. Columns labeled σ show residual standard deviation and depend on whether the M and R adjustment is used or not. Use $\sigma_{\log_{10}Y}$ with rearranged equations to give $\log_{10}Y$ in terms of MMI.

Atkinson and Kaka's (2007) relationships, shown in Eqs. 31 and 32, employ smaller dataset of California observations than Worden et al. (2012), but they reflect data from central and eastern and US observations. There are 986 observations: 710 from 21 California earthquakes, $M = 3.5\text{--}7.1$, $R = 4\text{--}445$ km, $\text{MMI} = \text{II--IX}$, and 276 central and eastern US observations from 29 earthquakes $M = 1.8\text{--}4.6$, $R = 18\text{--}799$ km. They include regression for $S_a(0.3 \text{ s}, 5 \%)$, $S_a(1.0 \text{ s}, 5 \%)$, $S_a(3.0 \text{ s}, 5 \%)$, PGA, and PGV. Equation 32 accounts for the apparent effects of magnitude M and distance R . As suggested by the difference between the columns for residual standard deviation, the information added by M and R only modestly reduces uncertainty. The Atkinson and Kaka (2007) relationships are not bidirectional, meaning that one cannot rearrange them to estimate ground motion as a function of MMI.

Units of Y are cm/s or cm/s², 5 % damping. Units of R are km. Columns labeled σ show residual standard deviation and depend on whether the M and R adjustment is used or not (Table 3).

Other GMICES of potential interest include the following. Wald et al.'s (1999) relationship draws on 342 (PGA, PGV, MMI) observations from eight California earthquakes. Kaestli and Faeh (2006) offer a PGA-PGV-MMI relationship for Switzerland, Italy, and France. Tselentis and Danciu (2008) offer relationships for MMI as functions of PGA, PGV, Arias intensity, cumulative absolute velocity, magnitude, distance, and soil conditions for Greece. Kaka and Atkinson (2004) offer GMICES relating MMI to PGV and three periods of PSA for eastern North America. Sørensen et al. (2007) offer a GMICE relating EMS-98 to PGA and PGV for Vrancea, Romania.

For relationships that give ground motion as a function of MMI (intensity to ground-motion conversion equations, IGMCE), consider Faenza and Michelini (2010) for Italy, Murphy, and O'Brien (1977) for anywhere in the world and Trifunac and Brady (1975) for the western United States. Unless explicitly stated, GMICE and IGMCE relationships are not

interchangeable – it is inappropriate to simply rearrange terms of a GMICE to produce an IGMCE. The reason is that both GMICE and IGMCE are derived by regression analysis. Given (x,y) data, a least-squares regression of y as a function of x will generally produce a different curve than a least-squares regression of x as a function of y .

Hazard Deaggregation

When evaluating the risk to an asset, it is often desirable to perform nonlinear dynamic structural analyses at one or more intensity measure levels. To do so, one needs a suite of ground-motion time histories scaled to the desired intensity. The ground-motion time histories should be consistent with the seismic environment. That is, they should reflect the earthquake magnitudes m and distances r that would likely cause that level of excitation in that particular place. The reason is that magnitude and distance affect the duration and frequency content of the ground-motion time history, which in turn affects structural response. See McGuire (1995) or Bazzurro and Cornell (1999) for more information.

There is another term (commonly denoted by ε) that also matters. It relates to how the spectral acceleration response at a specified period in a particular ground-motion time history differs from its expected value, given magnitude and distance. Let y denote the natural logarithm of the intensity measure level, e.g., the natural logarithm of the spectral acceleration response at the building's estimated small-amplitude fundamental period of vibration. Let μ and σ denote the expected value and standard deviation of the natural logarithm of the intensity measure level, respectively, calculated from a ground-motion prediction equation. The ε term is a normalized value of y , as follows:

$$\varepsilon = \frac{y - \mu}{\sigma} \quad (33)$$

When calculating the motion y_0 that has a specified exceedance probability p_0 , one labels the ε from a specific source and this particular value of motion y_0 as ε_0 . The equation is the same as

Eq. 33, except with the subscript 0 on y and ε . It is practical to calculate for a given location, intensity measure type, and intensity measure level, the contribution of each fault segment, magnitude, rupture location, and value of ε_0 to the frequency with which the site is expected to experience ground motion of at least the specified intensity measure level. In fact, Eq. 26 shows that the site hazard is summed from such values. (For simplicity that equation omits mention of ε , but the extension is modest.) See Baker and Cornell (2005) for more information.

Rather than leading the reader through the math, suffice it to say that there are online tools to do that hazard deaggregation, and an example is given here. The USGS offers a website that does interactive hazard deaggregation for the United States. As of this writing, the URL includes the year associated with the hazard model, so it will change over time. The most recent tool at this writing is <https://geohazards.usgs.gov/deaggint/2008/>. When that site becomes obsolete, the reader should be able to find the current one by googling “interactive hazard deaggregation USGS.”

Consider an imaginary 12-story building in San Diego, California at 1126 Pacific Hwy, San Diego CA, whose geographic coordinates are 32.7166 N -117.1713 E (North America has negative east longitude). Suppose its small-amplitude fundamental period of vibration is 1.0 s, its V_{s30} is 325 m/s, and its depth to bedrock (defined as having a shearwave velocity of 2,500 m/s) is 1.0 km. One wishes to select several ground-motion time histories with geometric mean $S_a(1.0 \text{ s}, 5 \%)$ equal to that of the motion with 10 % exceedance probability in 50 years. The input data look like Fig. 4. The results look like Fig. 5, which shows that 10%/50-year motion at this site tends to result from earthquakes with Mw 6.6 at 1.8 km distance and a value of $\varepsilon_0 = -1.22$. One can then draw sample ground-motion time histories with approximately these values of magnitude, distance, and ε_0 from a database such as PEER's strong motion database, currently located at http://peer.berkeley.edu/peer_ground_motion_database.

Beginner's Guide to Fragility, Vulnerability, and Risk, Fig. 4 USGS interactive hazard deaggregation website

Convenient Sources of Hazard Data

For California sites, see www.OpenSHA.org/apps for a very powerful hazard curve calculator. See <http://earthquake.usgs.gov/hazards/products/> for several sets of gridded hazard data from the National Seismic Hazard Mapping Program. For example, for the 2008 NSHMP hazard curves for $S_a(1.0 \text{ s}, 5 \%)$, see <http://earthquake.usgs.gov/hazards/products/conterminous/2008/data/> and look for the data file labeled “Hazard curve data 1 Hz (1.0 s).” If you use NSHMP’s hazard curves (as opposed to uniform seismic hazard maps), the data will reflect hazard on site class B, so adjust for other site classes. A good way to do that is by multiplying by the site coefficient F_a (for the 3.33 Hz or 5 Hz curves) or F_v (for the 1 Hz curves) from ASCE 7-10 Tables 11.4-1 and 11.4-2, respectively. You will also find at the

same location gridded uniform seismic hazard data such as the values of $S_a(1.0 \text{ s}, 5 \%)$ with 2 % exceedance probability in 50 years (the so-called MCE_G map). For that map, see the data file labeled “Gridded Hazard Map 1 Hz (1.0 s) 2 % in 50 Years” at <http://earthquake.usgs.gov/hazards/products/conterminous/2008/data/>. For elsewhere in the world, see www.globalquakemodel.org.

The risk analyst typically also needs a convenient and authoritative source of soil information. As of this writing, the USGS offers a global map of estimated average shearwave velocity in the upper 30 m of soil (V_s^{30} in ASCE 7-10 notation). See <http://earthquake.usgs.gov/hazards/apps/vs30/> or Google “Global V_s^{30} Map Server” for this useful resource. Find your latitude and longitude using Google Earth, then look up your

Beginner’s Guide to Fragility, Vulnerability, and Risk, Fig. 5 Sample output of the USGS’ interactive hazard deaggregation website

location at the USGS site by centering a grid around it, adding and subtracting 0.01 degrees of latitude and longitude for a Vs30 map about 2km × 2km grid centered at your location. See Wald and Allen (2007) for its technical basis. In the United States, the site data app at www.OpenSHA.org/apps is more powerful and easier to use. It offers the Wald-Allen Vs30 along with other sources, such as the Wills and Clahan (2006) map of Vs30 in California.

Risk for a Single Asset

Risk

This entry has dealt so far with fragility, vulnerability, and seismic hazard. Risk is analogous to hazard, but as used here it refers to the relationship between probability or frequency of the undesirable outcome and a measure of the degree of that undesirable outcome. If there are only two

possible values of that undesirable outcome – it occurs or it does not occur – one can apply the theorem of total probability, combining fragility and hazard, to estimate the mean frequency with which it occurs or the probability that it will occur in a specified period of time. If the undesirable outcome is measured in terms of loss, then one can apply the theorem of total probability, combining vulnerability and hazard, to estimate the mean annualized loss or the probability that at least a specified degree of loss will occur in a specified period of time. This entry deals with risk only for a single asset.

Expected Failure Rate for a Single Asset

Let $F(s)$ denote a fragility function for a component with a single damage state and let $G(s)$ denote the mean rate of shaking $S \geq s$ (mean number of events per year in which the shaking is at least s at the site of interest). The mean rate of failures (number of times per year that the

component reaches or exceeds the specified damage state) is given by

$$\lambda = \int_{s=0}^{\infty} -F(s) \frac{dG(s)}{ds} ds \quad (34)$$

where $G(s)$ = mean annual frequency of shaking exceeding intensity s . One can also use integration by parts and show that

$$\lambda = \int_{s=0}^{\infty} \frac{dF(s)}{ds} G(s) ds \quad (35)$$

If, for example, $F(s)$ is taken as a cumulate log-normal distribution function, $dF(s)/ds$ is the log-normal probability density function, i.e.,

$$\begin{aligned} F(s) &= \Phi\left(\frac{\ln(s/\theta)}{\beta}\right) \\ \frac{dF(s)}{ds} &= \phi\left(\frac{\ln(s/\theta)}{\beta}\right) \end{aligned} \quad (36)$$

Equation 34 only rarely can be evaluated in closed form. More commonly, $G(s)$ is available only at discrete values of s . If one has $n + 1$ values of s , at which both $F(s)$ and $G(s)$ are available, and these are denoted by s_i , F_i , and G_i ; $i = 0, 1, 2, \dots, n$, respectively, then Eq. 34 can be evaluated numerically by

$$\begin{aligned} \lambda &= \sum_{i=1}^n \left(F_{i-1} G_{i-1} (1 - \exp(m_i \Delta s_i)) \right. \\ &\quad \left. - \frac{\Delta F_i}{\Delta s_i} G_{i-1} \left(\exp(m_i \Delta s_i) \left(\Delta s_i - \frac{1}{m_i} \right) + \frac{1}{m_i} \right) \right) \\ &= \sum_{i=1}^n (F_{i-1} a_i - \Delta F_i b_i) \end{aligned} \quad (37)$$

where

$$\begin{aligned} \Delta s_i &= s_i - s_{i-1} \quad \Delta F_i = F_i - F_{i-1} \\ m_i &= \ln(G_i/G_{i-1})/\Delta s_i \quad \text{for } i = 1, 2, \dots, n \end{aligned}$$

$$a_i = G_{i-1} (1 - \exp(m_i \Delta s_i))$$

$$b_i = \frac{G_{i-1}}{\Delta s_i} \left(\exp(m_i \Delta s_i) \left(\Delta s_i - \frac{1}{m_i} \right) + \frac{1}{m_i} \right)$$

Equation 37 is exact for piecewise linear F and piecewise loglinear G .

Probability of Failure During a Specified Period of Time

If one assumes that hazard and fragility are memoryless and do not vary over time, then failure is called a Poisson process, and the probability that failure will occur at least once in time t is given by

$$P_f = 1 - \exp(-\lambda \cdot t) \quad (38)$$

where λ is the expected value of failure rate, calculated for example using Eq. 37.

Expected Annualized Loss for a Single Asset

Now consider risk in terms of degree of loss to a single asset. There are many risk measures in common use. First, consider the expected annualized loss (*EAL*). It is analogous to mean rate of failures as calculated in Eq. 34. If loss is measured in terms of repair cost, *EAL* is the average quantity that would be spent to repair the building every year. It can be calculated as

$$EAL = V \int_0^{\infty} y(s) \frac{-dG(s)}{ds} ds \quad (39)$$

where V refers to the replacement value of the asset and $y(s)$ is the expected value of loss given shaking s as a fraction of V . Equation 39 can only rarely be evaluated in closed form. More commonly, $y(s)$ and $G(s)$ are available at discrete values of s . If one has $n + 1$ values of s , at which both $y(s)$ and $G(s)$ are available, and these are denoted by s_i , y_i , and G_i ; $i = 0, 1, 2, \dots, n$, respectively, then *EAL* in Eq. 39 can be replaced by

$$\begin{aligned}
 EAL &= V \sum_{i=1}^n \left(y_{i-1} G_{i-1} (1 - \exp(m_i \Delta s_i)) \right. \\
 &\quad \left. - \frac{\Delta y_i}{\Delta s_i} G_{i-1} \left(\exp(m_i \Delta s_i) \left(\Delta s_i - \frac{1}{m_i} \right) + \frac{1}{m_i} \right) \right) \\
 &= V \sum_{i=1}^n (y_{i-1} a_i - \Delta y_i b_i)
 \end{aligned} \tag{40}$$

where

$$\begin{aligned}
 \Delta s_i &= s_i - s_{i-1} \quad \Delta y_i = y_i - y_{i-1} \\
 m_i &= \ln(G_i/G_{i-1})/\Delta s_i \quad \text{for } i = 1, 2, \dots, n
 \end{aligned}$$

$$\begin{aligned}
 a_i &= G_{i-1} (1 - \exp(m_i \Delta s_i)) \\
 b_i &= \frac{G_{i-1}}{\Delta s_i} \left(\exp(m_i \Delta s_i) \left(\Delta s_i - \frac{1}{m_i} \right) + \frac{1}{m_i} \right)
 \end{aligned}$$

Risk Curve for a Single Asset

It is often desirable to know the probability that loss will exceed a particular value during a given time period t as a function of loss. Here, that function is called a risk curve or a loss-exceedance curve. It is like the hazard curve, except that the x -axis measures loss instead of excitation. Suppose one knows the hazard curve and the uncertain vulnerability function for a single asset. Figure 6 shows an example. The risk curve for a single asset can be calculated as

$$R(x) = \int_{s=0}^{\infty} (1 - P[X \leq x | S = s]) \frac{dG(s)}{ds} ds \tag{41}$$

where

X = uncertain degree of loss to an asset, such as the uncertain damage factor,
 x = a particular value of X ,
 s = a particular value of the excitation, such as the shaking intensity in terms of the 5 % damped spectral acceleration response at some index period of vibration,

Beginner's Guide to Fragility, Vulnerability, and Risk, Fig. 6 Sample risk curve. The *solid line* is the risk curve; the *dotted line* shows that the asset experiences a damage factor of 0.13 with an average exceedance rate of 0.004

$R(x)$ = annual frequency with which loss of degree x is exceeded,

$G(s)$ = the mean annual frequency of shaking exceeding intensity s ,

$P[X \leq x | S = s]$ = cumulative distribution function of X evaluated at x , given shaking s

If X is lognormally distributed at $S = s$, then

$$P[X \leq x | S = s] = \Phi \left(\frac{\ln(x/\theta(s))}{\beta(s)} \right) \tag{42}$$

where

$\theta(s)$ = median vulnerability function, i.e., the value of the damage factor with 50 % exceedance probability when the asset is exposed to excitation s ,

$v(s)$ = coefficient of variation of vulnerability, i.e., the coefficient of variation of the damage factor of the asset exposed to excitation s ,

$\beta(s)$ = logarithmic standard deviation of the vulnerability function, i.e., the standard deviation of the natural logarithm of the damage factor when the asset is exposed to excitation s .

If one has the mean vulnerability function $y(s)$ and coefficient of variation of loss as a function of shaking $v(s)$, use Eqs. 6 and 7 to evaluate $\theta(s)$ and $\beta(s)$.

Suppose the analyst has $y(s)$, $v(s)$, and $G(s)$ at a number n of discrete values of s , denoted here by s_i , where i is an index $i \in \{1, 2, \dots, n\}$. One can numerically integrate Eq. 41 by

$$\begin{aligned} R(x) &= \sum_{i=1}^n \left(p_{i-1}(x) G_{i-1} (1 - \exp(m_i \Delta s_i)) \right. \\ &\quad \left. - \frac{\Delta p_i(x)}{\Delta s_i} G_{i-1} \left(\exp(m_i \Delta s_i) \left(\Delta s_i - \frac{1}{m_i} \right) + \frac{1}{m_i} \right) \right) \\ &= \sum_{i=1}^n (p_{i-1}(x) \cdot a_i - \Delta p_i(x) \cdot b_i) \end{aligned} \quad (43)$$

where

$$\begin{aligned} p_i(x) &= P[X \geq x | S = s_i] \\ &= 1 - \Phi \left(\frac{\ln(x/\theta(s_i))}{\beta(s_i)} \right) \end{aligned} \quad (44)$$

$$\Delta p_i(x) = p_i(x) - p_{i-1}(x) \quad (45)$$

$$\Delta s_i = s_i - s_{i-1} \quad m_i = \ln(G_i/G_{i-1})/\Delta s_i \quad \text{for } i = 1, 2, \dots, n$$

$$\begin{aligned} a_i &= G_{i-1} (1 - \exp(m_i \Delta s_i)) \\ b_i &= \frac{G_{i-1}}{\Delta s_i} \left(\exp(m_i \Delta s_i) \left(\Delta s_i - \frac{1}{m_i} \right) + \frac{1}{m_i} \right) \end{aligned}$$

Equation 43 is exact if $p(x)$ and $\ln G(s)$ vary linearly between values of s_i .

Probable Maximum Loss for a Single Asset

There is no universally accepted definition of probable maximum loss (PML) for purposes of earthquake risk analysis, but it is often understood to mean the loss with 90 % nonexceedance probability given shaking with 10 % exceedance probability in 50 years. For a single asset, PML can be calculated from the seismic vulnerability function by inverting the conditional distribution

of loss at 0.90, when conditioned on shaking with 10 % exceedance probability in 50 years.

For example, assume that loss is lognormally distributed conditioned on shaking s , with median $\theta(s)$ and logarithmic standard deviation $\beta(s)$ as described near Eq. 42, which are related to the mean vulnerability function $y(s)$ and coefficient of variation $v(s)$ as in Eqs. 6 and 7. Under the assumption of Poisson arrivals of earthquakes, shaking with 10 % exceedance probability in 50 years is the shaking with exceedance rate $G(s_{PML}) = 0.00211$ per year, so PML can be estimated as a fraction of value exposed by

$$PML = \theta(s_{PML}) \cdot \exp(1.28 \cdot \beta(s_{PML})) \quad (46)$$

where $s_{PML} = G^{-1}(0.00211 \text{ year}^{-1})$, that is, the hazard curve (events per year) inverted at 0.00211.

Conclusions

This entry has provided a primer on fragility, vulnerability, and risk for the student or professional who is new to the topic. It briefly introduced basic concepts of fragility, vulnerability, hazard, and risk. Fragility is used to relate excitation, such as ground motion, to the probability that some undesirable event will occur, such as the probability that a component will become nonfunctional or that a building will be damaged. In some situations, multiple fragility functions can apply to the same asset; the entry presented three distinct situations and presented several approaches to deriving fragility functions and some useful sources of fragility functions. Vulnerability relates excitation to the degree of loss, such as the uncertain repair cost to a building. Three distinct approaches exist to deriving vulnerability functions: empirical, analytical, and expert opinion, each with its advantages and disadvantages. This entry briefly summarized the approaches, though it did not provide detail.

Hazard relates the exceedance probability or exceedance frequency to various levels of excitation, such as the rate at which earthquakes occur causing or exceeding various levels of spectral

acceleration response. The entry introduced probabilistic seismic hazard analysis, distinguished probability from exceedance rate, summarized some leading measures of excitation and conversion between them, explained hazard deaggregation, and offered some convenient sources of hazard data. Risk relates the degree of loss to its rate of exceedance, or it can express long-term average loss. This entry presented methods for estimating and depicting risk for a single asset.

An Introduction: Evolution of Inelastic Design and Justification for Using a Behavior Factor for Extreme Transient Load Designs

The force-based design philosophy adopted by current design codes prescribes that the design of the structural system and the sizing and reinforcing of its structural elements are developed under prescribed equivalent statically applied forces. Structural design against seismic loads follows an ultimate limit state (ULS) design, since the excitation levels considered have very low probabilities of being exceeded. In this context, limit analysis of the structures is enforced possibly using a load factor and unfactored resistance approach or, in most cases, a partial factor – load and resistance factor – design approach (e.g., EC8 2004). Historically, earlier generations of seismic design codes adopted throughout the world a serviceability level approach, whereby the prescribed seismic loads were applied to the structure unfactored and the corresponding verification at the member level was evaluated using linear elastic analysis – including cracking, for reinforced concrete (RC) structures – and code prescribed allowable stress for the structural materials (concrete, reinforcement, structural steel or timber). These allowable stress limits were a factored percentage of the actual material strength and represented the safety factor built in the design inequality, since the loads were unfactored, thereby justifying linear elastic analysis. Such an allowable (working) stress force-based design has been the traditional design approach up until the 1970s in most seismically affected countries.

Direct inelastic design through limit analysis through the relaxation of the prevailing design assumption of an elastic response, accepting the fact that the structure can survive an extreme transient action by entering into the inelastic range in a controlled damage response, is traced in protective civilian designs against military action during World War II in England. Although plasticity theory, namely, the mathematical formulation of the ideal plastic flow of metal-type

Behavior Factor and Ductility, Fig. 1 (a) Baron J. Baker demonstrating the effectiveness of a model Morrison shelter to survive a collapsed building floor following a bomb hit, with controlled inelastic deformation in order to ensure survival of its occupants (http://en.wikipedia.org/wiki/Baron_Baker, also: <http://www-g.eng.cam.ac.uk/125/1925-1950/baker6.html>). (b) Picture of a Morrison shelter deployed inside a house for civilian protection (http://en.wikipedia.org/wiki/Morrison_shelter#cite_note-21)

materials, was well developed in the early nineteenth century, it was at this time that through the formulation of the plasticity theorems that limit analysis design methods for reduced loading capacity were adopted, for the design of simple steel structures for civilian protection under extreme blast loads (Fig. 1). Specifically for seismic loading and following the observation/evaluation of the response of simple structures following severe earthquakes in California in the 1950s, it was demonstrated by Housner (1956) that a sufficient inelastic deformation supply by the structure through controlled (hierarchical) underdesign of the elements and local detailing resulted in these structures behaving in an acceptable manner during the extreme earthquake event.

Taking therefore into account the transient time-varying nature of the loading and of the response, the type of the loading and inertia effects, and the extreme magnitude of the load intensity, a reduction factor was proposed to be used in order to reduce the design force (therefore resistance) of the structure to levels (often considerably) lower than those required for full elastic response, at the expense of increased inelastic global (structural) and local (element, section) deformations of a controlled magnitude and distribution. This reduction is enforced through

recognizing (and thereby enforcing) the fact that such an intentionally (or accidentally) underdesigned structure with adequate ductility capacity will survive the extreme loading event scenario with tolerable inelastic deformations, to a level that is acceptable for the safety of its occupants and equipment. As an extension of this initial collapse limitation design approach adopted in the 1970s, additional intermediate performance requirements for occupants and equipment have been adopted, leading to a complete performance-based design (PBD) philosophy for the safety and/or operability of the structure, occupants, and equipment.

In order to reduce the design load for elastic response, a factor greater than 1.0 is adopted, which, depending on the code, is denoted as: the behavior factor q (Europe), the response reduction coefficient or response modification factor R (United States and the Americas), the structural performance factor S_p (New Zealand), or the structural characteristic factor D_s (Japan), all these factors denoted as the behavior factor q herein, for simplicity. The magnitude of q , obtained for (design) or by (assessment) the quantification of the limiting structural resistance versus the magnitude of the corresponding inelastic global or local element, section, or material inelastic deformations (axial or shear strains, flexural rotations,

and so on) – expressed as the corresponding ductilities μ – and the interrelation of these two, is the topic of discussion of this entry.

The Behavior Factor: Its Types, Definitions, and Uses in Seismic Design

Behavior Factor for Ductility q_μ of SDOF Equivalent Structural Systems

The behavior factor for ductility (denoted as q_μ) of an inelastic SDOF system is defined, for a particular base excitation $g(t)$, as the ratio of its yield resistances R_y in order to develop two ductility levels, a prescribed ductility level $\mu = \mu_i$ and a ductility $\mu = 1.0$, namely, entirely elastic response (Eq. 1):

$$q_\mu(T_0, \xi, f(R, \mu), g(t), \mu_i) = \frac{R_y(\max|\mu| = 1.0)}{R_y(\max|\mu| = \mu_i)} \quad (1)$$

where q_μ , besides $g(t)$, depends on the initial elastic response parameters, namely, elastic period T_0 and critical damping ratio ξ , and on the parameters characterizing the inelastic response, namely, R_y and the cyclic hysteretic response shape $f(R, \mu)$.

Both terms of the fraction above are evaluated from time history integration of the equation of motion under the base excitation $g(t)$. Solution of the equation over a range of periods T_0 yields the ductility spectrum for the given earthquake excitation, also denoted as the q_μ – μ – T spectrum of this excitation. For design applications, such spectra are evaluated for an ensemble of base excitation inputs characterizing the local seismicity of the region and local soil effects; the resulting average plus percent fractile q_μ – μ – T spectrum is obtained for the design and evaluation of structures in the region exhibiting compatible hysteretic response characteristics and initial damping. The definition of q_μ and its dependence on structural and excitation parameters is discussed in section “Evaluation of the Behaviour Factor Due to Ductility q_μ of SDOF Systems” herein.

Behavior Factors for Seismic Design or Evaluation and Redesign of Structural Systems, q_d and q_s

The earliest use of a ductility reduction coefficient can be traced to the seismic design regulations in California, in which a force reduction coefficient was adopted depending on the building properties, namely, seismic resisting system and construction material. The 1959 edition of the Structural Engineers Association of California (SEAOC) Blue Book and its successive editions (e.g., SEAOC 1974) used this horizontal force factor K , in the context of an allowable stress design procedure, for the estimation of the design base shear. ATC (1978) was the first seismic design code that adopted an R factor greater than 1.00 as a divisor of the elastic design response spectrum (EDRS) forces, which depended on the type of structural system but was, as yet, independent of the building period. The early uses of R were based not only on SDOF analysis but, primarily, on consensus values through the earthquake engineering design community, with typical values of R and comparisons among different codes given in ATC (1995). Since then, the reduction coefficient R – initially as R_w , for codes based on working stress design methods such as UBC (1988) – has been adopted in all ultimate level design codes (e.g., NEHRP 1985; FEMA-356 2000; ASCE 2013). In Europe, Eurocode 8, from the initial stages of development (EC8 ENV 1988) up to the final completion (EC8 2004), also adopted the behavior factor q . To date, most modern force-based seismic design codes adopt the behavior factor approach for quantifying the seismic design forces, with different levels of rationalization for the magnitude of q (R) (see, for instance, an overview of R factors adopted in South American seismic design codes in Chavez et al. 2012).

Based on the way the behavior factor is applied in seismic design, one can identify two uses of q , namely: (i) q_d – specified for the design of new buildings in order to control the ductility demand (and thus damage level) for a given site seismicity and performance level. This is specified in the seismic codes as the maximum allowed behavior factor for the design of modern

Behavior Factor and Ductility, Fig. 2 Definition of the design and supplied (available) behavior factors q_d and q_s and the contributing q , for non-base-isolated structures: (i) q for ductility (q_μ), (ii) q for structural overstrength (q_Ω), and (iii) q for material strength reduction (q_m or q_w).

In the context of PBD, $q_{s,d}$ are no longer unique and depend on the local (and therefore global) ductility demands μ_I to μ_{IV} for different performance levels I to IV , respectively

structures. (ii) q_s – supplied (also called available) behavior factor of a given building (new or existing), corresponding to an anticipated elastic demand defined by the building period and the local EDRS, for a given ductility capacity and therefore damage level at specified performance levels (I – IV , Fig. 2) of this structure; for existing structures designed by past code generations, this behavior factor is usually below the currently enforced design q_d due to de facto underdesign coupled with insufficient or complete lack of ductile response of such structures.

Behavior Factor q_d for Seismic Design of New Structures

In the context of force-based seismic design, the design behavior factor q_d is a design force reduction coefficient greater than 1.0 by which the EDRS-specified base shear V_{ed} of the structure's equivalent SDOF system representation (Fig. 2) is divided, in order to establish the seismic design base shear level V_d of this structure (Eq. 2), expressed as the product of the seismic coefficient C_{sd} times the inertial weight W of the structure for the seismic load combination:

$$V_{yd} = \frac{V_{ed}}{q_d} = \frac{C_{sd}W}{q_d} \quad (2)$$

where the EDRS is representative of the local seismicity, earthquake return period, and system equivalent damping. Modern design typically codes specify for RC buildings the 5 % EDRS, giving suitable adjustment multipliers for systems with other damping coefficients such as steel, timber, or prestressed concrete (e.g., the EDRS modification coefficient $\eta = \sqrt{10/(5 + \xi)} \geq 0,55$ in EC8 (2004), where ξ is the percent critical damping).

Considering the typical base shear versus roof deformation response under increasing lateral load in Fig. 2, it can be seen that q_d can be expressed (Uang 1991; Whittaker et al. 1999) as the product of four behavior factors that relate the elastic base shear demand of the EDRS to the design base shear force as follows (Eq. 3):

$$q_d = q_\mu \cdot q_\Omega \cdot q_\xi \cdot \{q_m \text{ or } q_w\} \quad (3)$$

where:

- (i) q_μ is the behavior factor for ductility of the equivalent SDOF system, $q_\mu = V_{ed}/V_{ud}$: this

factor relates the elastic spectral base shear demand V_{ed} to the equivalent SDOF bilinear yield strength V_{ud} , obtained by assuming an elastoplastic equal area approximation of the inelastic base shear–roof displacement response under a given lateral load profile, up to the ultimate deformation δ_u . The value of this factor varies with the base excitation(s), the dynamic and inelastic hysteretic characteristics of the system (including structural damping), and its ductility. It corresponds to the basic design behavior q_s in EC8 (2004): for concrete structures q_s takes values between $1.5 < q_s < 3.0$ and $2.0 < q_s < 4.5$, for ductility classes medium and high, respectively. q_μ is established from SDOF analysis, as described in section “Evaluation of the Behaviour Factor Due to Ductility q_μ of SDOF Systems” of this work.

- (ii) q_Ω is the behavior factor for structural overstrength, $q_\Omega = V_{ud}/V_{yd}$, relating V_{ud} to the base shear V_{yd} at incipient onset of yield within the structural elements, at a roof deformation δ_y . The value of this factor, which in EC8 (2004) is defined as the ratio α_u/α_1 , accounts for the overstrength of the structure and depends on the type of structural system and the degree of redundancy built in the system: for instance, for a typical soft ground story pilotis structure with limited redistribution of inelastic actions in the members of the upper stories, this factor is close to 1.0. For medium-rise RC frame buildings, however, where seismic loads govern the design and members exhibit sufficient local ductility for redistribution, q_Ω is of the order of 1.5–1.8, while for fully infilled RC frames with good-quality masonry construction, q_Ω can easily reach values of 2.50 and higher (Repapis et al. 2006b). For low-rise RC frame buildings, overstrengths of 4.0 have been reported. This factor can be quantified through static or dynamic inelastic analysis

of the structure. Its magnitude and mode of evaluation are discussed in section “Building Behaviour Factor q_s ” herein.

- (iii) q_ξ is the behavior factor contribution due to increased critical damping ξ ; this contributing factor is meaningful for base-isolated or artificially damped systems, since the contribution of the initial mass proportional damping (rather than the hysteretic damping, which is included in q_u) is not as significant in non-base-isolated structures. This factor is therefore not considered further herein.
- (iv) q_m (or q_w) is the behavior factor due to material strength $q_m = V_{yd}/V_d$ or $q_w = V_{yd}/V_{dw}$, relating the base shear at incipient member yield V_{yd} to the design base shear level specified by the code V_d (for ULS design) or $V_{d,w}$ (for working stress design). This factor is practically the ratio of the material strength partial factor in load and resistance factor design, in order to relate the design material stress level (for EC2 2004, the characteristic strength f_{yk}) to the yield strength (f_{yd}) of the material controlling the response, namely, the steel reinforcement in modern structural RC designs; for EC2 (2004), $q_m = f_{yk}/f_{yd} = 1.15$. For buildings in Greece constructed during the 1970s using reinforcement with a yield strength of 400 MPa and designed for an allowable stress in flexural design calculations of 230 MPa with a 20 % increase for the seismic load combination, $q_m = 400/1.2 \cdot 230 = 1.45$ (Repapis et al. 2006a). It has been proposed that the factor q_m may also include strength gain due to strain rate effects, although this increase is not a factor to take into account since it is counterbalanced by strength reduction by cyclic degradation.

This behavior factor is implicitly taken into account in the design of new buildings and is of primary importance since it defines the

transition from allowable design level to peak member resistance in the assessment of existing buildings, in which their members may behave in a brittle manner with very little deformability reserves.

Behavior Factor q_s Supplied by an Existing Structure Under a Given EDRS

In the context of performance-based design (PBD), the available behavior factor q_s supplied by an existing structure can also be established for a given EDRS demand and at specific performance limits of damage. The structure may have been designed using a prescribed design behavior factor q_d (different than q_s) or none at all, as the case is for older existing buildings which have been designed using past force-based design philosophies (e.g., working stress).

The available behavior factor q_s of the structure *as is* (often reevaluated after strengthening and/or rehabilitation of the structure at hand) is evaluated (i) through dynamic analyses of the structure until the establishment of a collapse base excitation, which is then compared to the design base excitation of the currently enforced EDRS for this type of structural system, or (ii) through static inelastic analyses of the structure, using an often idealized bilinear approximation of the resulting base shear resistance–roof deformation capacity curve under an imposed lateral deformation. Following an initial idealization of the structure as an equivalent SDOF system, with a yield resistance equal to the base shear at the onset of yielding in the building and an effective period equal to the initial secant stiffness from the lateral pushover curve, q_s is the behavior factor which results in a ductility demand equal to the ductility actually supplied by the system equivalent SDOF system. Contributions to q_s in this case are accounted from the structure overstrength or the member overstrength due to material q_m , relating the yield strength (also obtained from in situ evaluation of material capacity) to the design strength.

Evaluation of the Behavior Factor Due to Ductility q_μ of SDOF Systems

The response of nonlinear SDOF systems under seismic excitation has traditionally been formulated in the form of $q_\mu-\mu-T$ (or $R_\mu-\mu-T$) spectra, representing an extension of earlier uses of such spectra, relating the ratio of yield to elastic resistance of the SDOF system (q_μ) to the corresponding displacement ductility μ , under blast-type loads (Biggs 1964). Such inelastic response spectra (also known as shock spectra) have been formulated for different time-varying forcing shapes, such as impulse, triangular, or half sine, and are widely used in military and protective designs for blast. As discussed in the introduction, the use of such design load reductions has been well established in the design of protective structures against blast, where the introduction of a factored elastic design for controlled inelastic deformation was initially introduced.

The mathematics for the evaluation of the dynamic response of SDOF systems under seismic excitation is well established in textbooks of structural dynamics (Clough and Penzien 1975) and is not covered herein. The peak ductility demand μ of a given inelastic system under a certain type of base (or force) excitation is obtained by step-by-step integration using explicit or implicit time integration procedures, depending on the duration of the forcing function. From the way the problem is posed in Eq. 1, given the SDOF characteristics (R_y, T_0, ξ, f, g), only the peak ductility can readily be estimated. Consequently, the numerical estimation of the $q_\mu-\mu-T$ for a prescribed ductility $\mu = \mu_i$ is necessarily an iterative process, involving successive iterative estimates of R_y and solution of the equation of motion to establish $R_y(\max|\mu| = \mu_i)$, for which the SDOF system attains a peak ductility $\mu = \mu_i$, e.g., using a variable bound bisection iterative solution scheme, to within a user-specified tolerance. Subsequent application of the procedure for $\mu = 1$ as well (elastic response) will establish

Behavior Factor and Ductility, Fig. 3 Indirect methods: Variation of q with period for ductility $\mu_i = 4$ from the construction of the EDRS and the IDRS spectrum of the design base shear coefficient C_y , according to the graphic methodology by Newmark and Hall (1973)

$R_y(\max|\mu| = 1)$ and q_μ . It should be noted that in the case of strongly softening systems which are representative of structures with severe second-order effects or strength degradation, such an iterative solution may not converge, implying that the SDOF system may never attain this target ductility.

Indirect Evaluation Methods

For seismic design, the evaluation of the behavior factor through the formulation of an inelastic design response spectrum (IDRS) shape for a given seismicity condition – expressed in the form of a peak ground acceleration (PGA), ground velocity (PGV), and ground displacement (PGD) at the site – has initially been based on indirect methods. Such methods specified amplification factors for the establishment of an EDRS and subsequent spectral reduction factors (i.e., period-dependent behavior factors) for constructing the IDRS. This approach was initially recognized by Veletsos and Newmark (1960), yet, later on, Newmark and Hall (1973) formulated the procedure for the construction of

the IDRS. Such indirect methods essentially provide $q_\mu(\mu, T)$ relations, as a function of target μ_i , for an assumed damping and form of inelastic hysteretic response (initially an elastic perfectly plastic (EPP) oscillator was considered).

Following estimations of SDOF inelastic response assuming EPP behavior and using limited accelerogram data available at the time, Newmark and Hall (1973) observed that (Fig. 3) (i) elastic and inelastic SDOF systems with sufficiently medium-to-long periods (medium-to-low frequencies) tend to displace equally and, consequently, the behavior factor is equal to the required ductility, (ii) elastic and inelastic SDOF systems with very short period (very high frequency) have spectral accelerations (and thus force demands) equal to the PGA and should be designed to remain elastic, and (iii) in between, the energy absorbed by an inelastic system having a yield strength $1/q_\mu$ of the elastic demand and, as a consequence, deforming to a target μ_i is nearly equal to the kinetic energy absorbed by the elastic SDOF system, thereby leading to an equal energy criterion between q_μ and μ_i (Fig. 3).

Behavior Factor and Ductility, Table 1 Period dependent response reduction coefficients q_μ following the Newmark and Hall (1973) procedure

Soil class	I			II			III		
EDRS region	<i>D</i>	<i>V</i>	<i>A</i>	<i>D</i>	<i>V</i>	<i>A</i>	<i>D</i>	<i>V</i>	<i>A</i>
$\mu_i = 1.5$	1.62	1.70	1.44	1.58	1.66	1.50	1.78	1.94	1.47
$\mu_i = 2.0$	2.28	2.21	1.76	2.16	2.19	1.83	2.46	2.70	1.79
$\mu_i = 5.0$	5.63	4.59	2.84	5.04	4.63	2.91	5.82	5.96	2.85

They therefore proposed the indirect construction of an IDRS from an EDRS, for a given target

ductility μ_i , using the following period-dependent response reduction coefficients q_μ (Eq. 4):

$$\begin{aligned}
 0 \leq T < T_1/10 & \quad q_\mu = 1 \\
 T_1/10 \leq T < T_1/4 & \quad q_\mu = \sqrt{2\mu_i - 1} \left(\frac{T_1}{4T} \right)^{2.513 \log \left(\frac{1}{\sqrt{2\mu_i - 1}} \right)} \\
 T_1/4 \leq T < T'_1 & \quad q_\mu = \sqrt{2\mu_i - 1} \\
 T'_1 \leq T < T_1 & \quad q_\mu = \mu_i \frac{T}{T_1} \\
 T_1 \leq T < T_2, \quad T_2 \leq T < 10 \text{ s} & \quad q_\mu = \mu_i
 \end{aligned} \tag{4}$$

where T_1 , T'_1 , and T_2 are the characteristic corner periods of the EDRS, defined from the peak ground response parameters (Newmark and Hall 1973):

$$\begin{aligned}
 T_1 &= 2\pi \frac{\phi_{ev} PGV}{\phi_{ea} PGA}, \quad T_2 = 2\pi \frac{\phi_{ed} PGD}{\phi_{ev} PGV}, \\
 T'_1 &= T_1 \cdot \frac{\sqrt{2\mu_i - 1}}{\mu_i}
 \end{aligned} \tag{5}$$

where ϕ_{ea} , ϕ_{ev} , ϕ_{ed} are the amplification factors defining the EDRS acceleration, velocity, and displacement from the corresponding PGA , PGV , and PGD for the site, defined by local seismicity considerations. Thus, in a log-log format, the Newmark and Hall q_μ - μ - T relation consisted of two constant q_μ regions (Eq. 4) followed by intermediate linear transitions, as shown in Fig. 3. Based on a statistical parameter evaluation, they recommended averaged relations of PGV/PGA (48 in/s/g) and PGD/PGV^2 (6 s/in.) and ϕ_{ea} , ϕ_{ev} , ϕ_{ed} equal to 2.6, 1.9, and 1.4, respectively, for the construction of the EDRS at 5 % damping; different amplification values were given for stiff or soft soil or, in addition to the average values above, for average plus or minus one standard deviation.

Successive improvements of the indirect q_μ - μ - T construction model were proposed by Newmark and colleagues (for a review of the literature, see Miranda and Bertero 1994) (i) using additional ground motions and including the vertical excitation, (ii) for wider sets of critical damping ratios ξ (2–10 %) and target ductilities μ_i (1–10), and (iii) for different hysteretic shapes $f(u, t)$.

Riddell (1995) extended the indirect method of evaluating q_μ for different soil classification conditions, by considering 72 accelerograms which were obtained during the 1985 Chile earthquake, initially classified according to the prevailing soil conditions as records on rock (I), firm (II), and medium stiffness (III) soil sites. Following statistical analysis, soil-dependent corner frequencies and amplification values Ψ_μ were proposed for obtaining the 5 % damping EDRS and the ductility-dependent IDRS, given the site PGA , PGV , and PGD , following the Newmark and Hall (1973) procedure. Based on the amplification factors reported, typical q_μ , evaluated as $q_\mu = \Psi_{\mu=1}/\Psi_\mu$ for $\mu_i = 1.5$, 2.0, and 5.0, are given below for the constant displacement (D), velocity (V), and acceleration (A) regions of the EDRS (Table 1):

Direct Evaluation Methods of q_μ

Since the indirect evaluation of the behavior factor intrinsically included the uncertainty of both the elastic spectral amplification as well as the inelastic reduction, the scatter between target and actual ductilities or strength demands was high. Furthermore, use of a constant q_μ over a period range or over the entire period range, as originally adopted in ATC (1978), was shown to be inadequate to limit the inelastic demands of SDOF systems, particularly for near-field earthquake events with severe velocity pulses (Mahin and Bertero 1981).

Consequently, direct methods of evaluating the behavior factor variation with period and ductility have been proposed, through statistical evaluation of SDOF time history analysis results. According to the direct estimation methodology, the elastic and inelastic response of a set of nonlinear SDOF oscillators over a period range was evaluated under a set of earthquake excitations and given oscillator characteristics, and the ratio of the required resistance of the system to remain elastic over that to develop a given ductility, as defined in Eq. 1, was evaluated in each case. The resulting variation of this ratio (q_μ) over the period range considered was statistically processed in order to establish $q_{\mu-\mu-T}$ functional relations that directly fitted the corresponding spectra for the specific record(s) and oscillator characteristics. Although average prediction functions were often reported, several studies also gave sensitivity analyses or even additional equations to obtain the mean plus standard deviation approximation of the data.

An examination of the indirect method above for the construction of the EDRS and IDRS reveals the physical requirements for the variation of q_μ with period for a given ductility μ_i (Newmark and Hall 1973):

- (i) For very stiff systems, the SDOF system cannot develop any ductility and is therefore elastic; consequently, any functional describing a $q_{\mu-\mu-T}$ variation must satisfy:

$$\lim_{T \rightarrow 0} q_\mu = 1$$

- (ii) For flexible long-period systems, the SDOF deformation of the elastic and the inelastic systems is equal to the imposed ground displacement; consequently q_μ is equal to the SDOF ductility:

$$\lim_{T \rightarrow \infty} q_\mu = \mu$$

- (iii) In between, in the so-called constant velocity region, energies of the elastic and the inelastic systems are comparable. Direct and indirect methods of establishing q_μ yield different requirements in this range.

Therefore, functional relations describing q_μ in terms of period and ductility should satisfy these requirements. Such statistical estimations of q_μ have shown that the latter limit is actually approached asymptotically from above (Nassar and Krawinkler 1991); however, the constraint imposed by the first limit has been relaxed in certain statistical studies in order to obtain better statistical correlations of $q_{\mu-\mu-T}$ in the short period (Riddell 1995). A brief description of several such functional relations and the corresponding parametric studies involved are given herein; a graphical comparison of the different $q_{\mu-\mu-T}$ spectral models for target ductilities $\mu_i = 4$ and 6 is given in Fig. 4, as proposed by these studies.

Influence of the SDOF oscillator inelastic characteristics. One of the earliest proposed $q_{\mu-\mu-T}$ expression that satisfied the functional limitations of the reduction factor spectrum by Newmark and Hall (1973) was the exponential function proposed by Nassar and Krawinkler (1991). In their statistical study, they considered 36 records to establish the attenuation of the ground motion parameters and 15 records from Western US earthquakes on firm-to-medium stiffness soils (plus 10 records from the Whittier Narrows earthquake, for verification) to establish q_μ . Two hysteretic shapes were considered to

Behavior Factor and Ductility, Fig. 4 Comparison of different q_μ - μ - T models for evaluating the behavior factor, for target ductilities of (a) $\mu_i = 4$ and (b) $\mu_i = 6$

model the hysteresis curve of the SDOF oscillator, namely, an EPP and a bilinear stiffness

degrading model. The q_μ - μ - T expression proposed is given in Eq. 6:

$$\begin{aligned}
 q_\mu(T, \mu, \alpha) &= (c \cdot (\mu_i - 1) + 1)^{1/c} \\
 \text{Elastoplastic systems } (\alpha = 0) \quad c(T) &= \frac{T}{T+1} + \frac{0.42}{T} \\
 \text{Elasto-hardening systems } (\alpha = 0.02) \quad c(T) &= \frac{T^{1.01}}{T^{1.01} + 1} + \frac{0.37}{T} \\
 \text{Elasto-hardening systems } (\alpha = 0.10) \quad c(T) &= \frac{T^{0.8}}{T^{0.8} + 1} + \frac{0.29}{T}
 \end{aligned} \tag{6}$$

The authors concluded that, with the exception of the short-period range, the stiffness degrading models with no hardening exhibited a 20 % higher behavior factor compared to the EPP system, with the effect diminishing for the 10 % hardening slope EPP and degrading oscillators. Furthermore, in addition to the quantification of the oscillator bias and based on the attenuation studies and the evaluation of the corresponding q_μ for the subject datasets, they further established that q_μ of SDOF systems for given μ_i is not sensitive to the epicentral distance of the earthquake and the ground motion; this observation, however, is considered in more detail further on.

Lee and Han (1999) developed direct expressions of q_μ for stiff soil and rock sites only, namely, soils exhibiting a shear-wave velocity larger than 750 m/s. In order to evaluate the

influence of the hysteretic response, they performed a statistical analysis of q_μ - μ - T using 40 ground motion records taking into account five different SDOF oscillator hysteretic shapes, namely, (i) EPP oscillator, (ii) bilinear hysteretic oscillator, (iii) degrading strength hysteretic oscillator, (iv) degrading stiffness oscillator (centered upon reversal), and (v) pinching hysteretic oscillator (in all cases initial damping of 5 % was assumed). They concluded that in the absence of the soil bias, additional factors that affect the q_μ demand (given target ductility and period) are the hardening slope and the form and extent of pinching of the oscillator cyclic characteristic, in a statistically independent manner to each other. They subsequently proposed a q_μ - μ - T functional in terms of the hysteretic parameters α_1 , α_2 , α_3 , and α_4 (Eq. 7):

$$\begin{aligned}
q_\mu &= (0.99 \cdot \mu + 0.15) \left(1 - e^{-23.69 \cdot T \cdot \mu^{-0.83}} \right) \cdot C_{\alpha 1} \cdot C_{\alpha 2} \cdot C_{\alpha 3} \cdot C_{\alpha 4}, \text{ with :} \\
C_{\alpha 1} &= 1.0 + (2.07 \cdot \ln(\mu) - 0.28) \cdot \alpha_1 - (10.55 \cdot \ln(\mu) - 5.21) \cdot \alpha_1^2 \\
C_{\alpha 2} &= \frac{1}{(0.2 \cdot \mu + 0.42) \cdot \alpha_2 + 0.005 \cdot \mu + 0.98} \\
C_{\alpha 3} &= \frac{0.85 + (0.03 \cdot \mu + 1.02) \cdot \alpha_3}{1 + (0.03 \cdot \mu + 0.99) \cdot \alpha_3 + 0.001 \cdot \alpha_3^2} \\
C_{\alpha 4} &= \frac{1}{1 + 0.11 \cdot e^{(1.4 \ln(\mu) - 6.6) \cdot \alpha_4}}
\end{aligned} \tag{7}$$

where α_1 measures the hardening slope, α_2 measures the strength degradation upon reversal, α_3 measures the stiffness degradation, and α_4 measures the pinching response.

Influence of the local soil conditions. Miranda (1993) and Miranda and Bertero (1994) considered a wide dataset of ground motion excitations which had been previously classified according to the relevant earthquake parameters (magnitude, distance from the fault) and the local soil conditions prevalent at the site. Statistical equations of q_μ in terms of the local soil conditions were subsequently obtained, proposing the following q_μ - μ - T evaluation function for different soil classifications (Eq. 8):

$$\begin{aligned}
q_\mu &= 1 + \frac{\mu_i - 1}{\Phi(T)} \\
\text{Rock sites} \quad \Phi(T) &= 1 + \frac{1}{10T - \mu_i T} - \frac{1}{2T} e^{-\frac{3}{2}(\ln T - 3/5)^2} \\
\text{Alluvium sites} \quad \Phi(T) &= 1 + \frac{1}{12T - \mu_i T} - \frac{2}{5T} e^{-2 \cdot (\ln T - 1/5)^2} \\
\text{Soft soil sites} \quad \Phi(T, T_s) &= 1 + \frac{T_s}{3T} - \frac{3T_s}{4T} e^{-3 \left(\ln \left(\frac{T}{T_s} \right) - 1/4 \right)^2}
\end{aligned} \tag{8}$$

where, apart from the parameters defined already, the dominant soil period T_s was introduced for the soft soil sites. The analysis showed that there is a distinct trend in the shape of the q_μ - μ curves for (primarily soft) soils that exhibit a predominant period, whereby in the vicinity of the oscillator resonance with the soil dominant period T_s ($T/T_s \sim 1$), the behavior factor q_μ is much larger than the target ductility (e.g., $q_{\mu i=3} = 8.5$ or $q_{\mu i=5} = 18.0$ was obtained); this effect led to

conservative designs based on the q_μ - μ - T relations obtained on firm ground or alluvia proposed by other studies, while for lower T/T_s values, the opposite was observed, with the reduction factors in this case being lower than μ_i (e.g., $q_{\mu i=3} = 2$ or $q_{\mu i=5} = 2.8$ at $T/T_s = 0.5$). Finally, for normalized periods above T_s ($T/T_s > 2$), the behavior factor was close to the target ductility, as for stiff soils and rock, yielding similar or conservative designs compared to the use of rock spectra.

In order to investigate the influence of stiffness degradation on soft soils, Miranda and Ruiz-Garcia (2002) extended this study by expressing q_μ in terms of the structural period normalized by the predominant soil period T_s (namely, q_μ - μ - T/T_s), using a set of 116 ground motions on soft-to-medium soils and two hysteretic systems, a bilinear EPP and a stiffness degrading. It was shown that the influence of stiffness degradation was significant for soft soil excitations, since for period ratios lower than soil resonance, in the range of $T/T_s \sim 2/3$ (also depending on μ_i), the average q_μ of stiffness degrading systems was about 25 % lower than q_μ of EPP systems, leading to unconservative designs based on the q_μ - μ - T relations obtained on firm ground for EPP systems. On the contrary, q_μ of stiffness degrading systems at soil resonant periods and above was higher than that for EPP systems, indicating that the earlier onset of nonlinearity in these structures induced a drop in the required R_y for a given target ductility compared to EPP structures.

Vidić et al. (1994) expressed q_μ versus ductility relations in site-specific form, expressed in

terms of the accelerogram's frequency parameter T_I , obtained at the period of change in slope of the idealized bilinear approximation of the pseudovelocity response spectrum $PS_v(T, \xi)$ of the accelerogram. For their analyses they considered 24 records from California, Chile,

Italy, Montenegro, and the 1985 Mexico City earthquake, analyzing SDOF oscillators with either EPP or stiffness degrading characteristics, yielding the more general q_μ - μ - T exponential expression of Eq. 9 (a tangent stiffness proportional damping equal to 5 % critical was used):

$$\begin{aligned}
 & T < T_0 & q_\mu &= c_1(\mu_i - 1)^{c_R} \cdot \frac{T}{T_0} + 1 \geq 1,0 \\
 & T_0 \leq T & q_\mu &= c_1(\mu_i - 1)^{c_R} + 1 \\
 & \text{where :} & T_0 &= c_2 \cdot \mu^{c_T} T_1 \\
 & \text{and :} & & \\
 & \text{stiffness degrading SDOF :} & c_1 & \quad c_2 \quad c_R \quad c_T \\
 & \text{elastoplastic SDOF :} & 0,75 & \quad 1,0 \quad 0,65 \quad 0,30 \\
 & & 1,10 & \quad 0,95 \quad 0,75 \quad 0,20
 \end{aligned} \tag{9}$$

In the context of PBD, Fajfar (1999) proposed more simplified conservative design envelopes for the estimation of the required target ductility

at a given q_μ (Eq. 10), by adapting the statistical q_μ - μ - T estimations by Vidić et al. (1994) above in the N2 method:

$$\begin{aligned}
 & T < T_0 & q_\mu &= (\mu_i - 1) \cdot \frac{T}{T_0} + 1 \geq 1,0 \\
 & T_0 \leq T & q_\mu &= \mu_i \\
 & \text{where :} & T_0 &= 0,65 \cdot \mu^{0,3} T_c \leq T_c \\
 & \text{or, in a simplified form :} & T_0 &= T_c
 \end{aligned} \tag{10}$$

This expression has been adopted with refinements (soil effect, softening or hardening oscillator characteristics) as the displacement coefficient method (DCM) for PBD (NEHRP 1985; FEMA-356 2000), where q_μ is equal to the coefficient C_I in the target roof estimation equation.

Riddell (1995) examined the influence of local soil conditions on q_μ using 72 records obtained during the Magnitude 7.8 1985 Chile earthquake and aftershocks on rock (I), hard (II), or medium soil (III), as also previously described in the indirect evaluation method for q_μ : following the indirect method analysis and recognizing that the variation in q_μ was high, direct evaluation

expressions for spectral amplification factors $\Psi(T, \mu)$ and therefore q_μ in terms of ductility and period were also proposed, as being more reliable and less prone to statistical scatter than the former indirect method. The function proposed was of the exponential form given in Eq. 11 using five statistical parameters (α_1 - α_5) – although a dominant soil period was not explicitly considered (type IV soft soil records were not available).

$$\begin{aligned}
 q_\mu &= \frac{S_a(T, \mu = 1)}{S_a(T, \mu = \mu_i)}, \text{ where} \\
 \Psi(T, \mu = \mu_i) &= \frac{\alpha_1 + \alpha_2 \cdot T^{\alpha_3}}{1 + \alpha_4 \cdot T^{\alpha_5}}
 \end{aligned}$$

Soil Type	$\mu_i = 2$					$\mu_i = 5$					(11)
	a_1	a_2	a_3	a_4	a_5	a_1	a_2	a_3	a_4	a_5	
I	0,45	5,81	0,66	18,0	2,04	0,60	4,75	0,86	37,3	2,03	
II	0,88	7,77	1,39	24,2	2,79	0,84	1,41	1,44	13,6	2,52	
III	-33,96	35,65	0,005	1,4	2,62	0,86	0,06	2,967	2,303	2,72	

The parameters were obtained from regression analysis after relaxing, for the sake of improved statistical correlation, the requirement that $\Psi(T, \mu)$ should be equal to 1.0 for rigid structures.

Ordaz and Pérez-Rocha (1998) considered the direct evaluation of q_μ as a force reduction parameter from the elastic relative displacement spectrum S_d , since both the inelastic and elastic displacements of the SDOF system are related to the ductility and q_μ , the variation of S_d with period being the controlling factor for the variation of q_μ , and also S_d

includes local soil effects. They therefore proposed a functional for q_μ in terms of the spectral displacement amplification S_d/PGD instead of T (Eq. 12) since, implicitly, it is a function of the period T . For their statistical analysis, they considered 445 records over a wide range of magnitudes, epicentral distance, and local soft soil to rock conditions.

$$q_\mu = 1 + (\mu_i - 1) \cdot \left(\frac{S_d(T)}{PGD} \right)^{\beta(\mu)}, \text{ where} \\ \beta(\mu) = 0.388 \cdot (\mu - 1)^{0,173}$$

Soil Type	$\mu_i = 2$			$\mu_i = 4$			$\mu_i = 6$			(12)

III	2,35	1,69	0,0418	1,03	1,24	0,2707	1,85	,821	0,1184	

Their expression $q_{\mu-\mu-S_d(T)/PGD}$ yielded similar results as the proposed direct $q_{\mu-\mu-T}$ relations by other investigators (e.g., Nassar and Krawinkler (1991) or Miranda (1993)), for either firm or soft soil, yet, unlike previous studies, is of a more general applicability over the entire range of soil types considered.

Watanabe and Kawashima (2002) investigated in detail the scattering of q_μ from the mean value as well as the influence of initial damping under elastic and EPP inelastic response, using 70 free-field records from a relatively large dataset from Japanese earthquakes: ground motions were classified according to different soil conditions with predominant soil period T_g , following the Japanese seismic design

code classification. They showed that their predictions of the average $\bar{q}_\mu$ approach reasonably well the equal energy and equal displacement approximation (Fig. 3). However, the average minus one standard deviation (σ_{q_μ}) values differ significantly from this simplification and on the unconservative side, since (σ_{q_μ}) increases disproportionately, and therefore, the use of $\bar{q}_\mu$ for design may be unconservative, especially for larger target ductilities. They then proposed an exponential $q_{\mu-\mu-T}$ relation and the corresponding expression for σ_{q_μ} in Eq. 13:

$$q_\mu = 1 + (\mu_i - 1) \cdot \Psi(T), \text{ where} \\ \Psi(T) = 1 + c \cdot \frac{T - a}{e^{b(T-a)}}, c = \frac{1}{(a \cdot e^{ab})}$$

Soil Type	$\mu_i = 2$			$\mu_i = 4$			$\mu_i = 6$

B

and $\sigma_{q_\mu} \sim 0.4 \cdot \mu_i - 0.3$ (all soil classes)

Additional soil-dependent $q_{\mu}-\mu-T$ functions were proposed by Genshu and Yongfeng (2007) with a range of application of μ_i between 1.0 and 6.0 and a period range between 0.1 and 6.0 s. A dataset of 370 records was used, divided according to the prevailing soil conditions at the site and classified in accordance with the four soil-type classifications adopted in the Chinese seismic code. Four different hysteretic oscillator characteristics were considered, namely, (i) an EPP model, (ii) a bilinear with hardening (5 %, 10 %, and 20 % hardening stiffness) and pinching

hysteresis, (iii) a shear slip model, and (iv) a bilinear elastic oscillator, in order to establish the influence of energy absorption. Three critical damping ratios were considered, namely, undamped, 3.5 % critical, and 5 % critical. Following a sensitivity study, the resulting $q_{\mu}-\mu-T$ spectra were correlated to the ratio of T/T_g , where T_g is the characteristic ground motion period of each record, defined as the period at which q_μ was maximized. They therefore proposed expressions with T for the estimation of q_μ with 90 % confidence, $q_{\mu,90}$ (Eq. 14):

$$q_{\mu,90} = \begin{cases} 1 + 0.36 \cdot \left[(2.5 \cdot \mu_i - 2)^{0.75} - 1 \right] \cdot \left(\frac{T}{T_g} \right)^{(0,6 - T/T_g)}, & 0 < T \leq 0.6 T_g \\ 1 + \left[(2.5 \cdot \mu_i - 2)^{0.75} - 1 \right] \cdot \left(\frac{T}{T_g} \right)^2, & 0.6 T_g < T \leq T_g \\ (2.5 \mu_i - 2)^{0.75} - \left[(2.5 \mu_i - 2)^{0.75} - 0.5 - 0.6 \mu_i \right] \left(\frac{T_g - 1}{\chi - 1} \right)^{2/\mu_i}, & T_g < T \leq \chi T_g \\ 0.5 + 0.6 \cdot \mu & , \chi \cdot T_g < T \end{cases} \quad (14)$$

Soil Type	A	B	C	D
χ	1.5	2.1	2.5	3.0

where χ is a coefficient depending on the soil class. Their statistical analysis confirmed that expressing q_μ in terms of the ratio T/T_g reduced the statistical scatter, making the governing parameter the target ductility; little influence of the critical damping and the hysteretic shape, apart from the short-period range, was observed on the magnitude of q_μ .

Influence of seismological and ground motion characteristics for near-field excitations. So far, the overall consensus of the SDOF

studies reported has been (and the statistics proved it so) that the earthquake magnitude was not a governing parameter for the quantification of q_μ , thereby the effort for parameter identification concentrated on the target ductility, the oscillator hysteretic shape, the damping, and, primarily, the soil characteristics and its predominant period.

Mavroeidis et al. (2004) investigated further the seismicity bias by considering the pulse duration T_p of near-field ground motions and

its effect on the strength demands for a given μ_i of EPP systems. The pulse duration observed in near-field records was shown on geophysical (source mechanism) terms to be about twice the rise time of the rupture process generating the earthquake, namely, the time it takes for a point on the fault to reach the maximum fault displacement, which, therefore, was well

correlated to the earthquake moment magnitude M_w . Subsequent inelastic SDOF analyses using near-field pulses demonstrated that T_p was an important parameter for near-field events, particularly through the establishment of amplification factors along the lines of a modified Eq. 4 (Newmark and Hall 1973), in terms of T/T_p (Eq. 15):

$$q_\mu = \begin{cases} 1 & \frac{T}{T_p} < \left(\frac{T}{T_p}\right)_a \\ \sqrt{2\mu_i - 1} & \left(\frac{T}{T_p}\right)_b < \frac{T}{T_p} < \frac{\sqrt{2\mu_i - 1}}{\mu_i} \left(\frac{T}{T_p}\right)_c \\ \mu_i & \frac{T}{T_p} > \left(\frac{T}{T_p}\right)_c \end{cases}$$

where:

M_w	$\left(\frac{T}{T_p}\right)_a$	$\left(\frac{T}{T_p}\right)_b$	$\left(\frac{T}{T_p}\right)_c$	ϕ_{ev}	ϕ_{ea}
5.6 – 6.3	0.035	0.35	0.75	2.10	0.95
6.4 – 6.7	0.010	0.2	0.75	2.0	0.75
6.8 – 7.6	0.002	0.055	0.75	1.55	0.43

(15)

Gillie et al. (2010) also considered the sensitivity of the q_μ - μ - T relations of EPP systems on the fault directivity effects in near-field earthquake motions, namely, the content of a strong velocity pulse. Their study was based on a dataset of 82 near-field acceleration records with velocity pulse content due to fault directivity effects. They demonstrated that, in the near-field case, unlike the prevailing notions on published q_μ - μ - T functionals from statistical analysis of both near- and far-field events, there was a much stronger dependence of q_μ on the earthquake magnitude and a much smaller dependence on the local soil conditions. Recognizing this dependence, they therefore examined the dependence of q_μ to the predominant period T_p of the velocity pulse content or, equivalently, to T_{RSV} , the period at the peak velocity of the elastic velocity spectrum, which was found to be the influencing parameter for the magnitude of q_μ . Overall, near-field events were proven to demand by the SDOF oscillators

lower q_μ than those with no directivity effects, such as those considered by previous q_μ - μ - T relations proposed so far in the literature. They therefore also proposed q_μ relations for near-field seismic events in terms of M_w (range of 6.0–7.5), since both T_p and T_{RSV} are not known a priori for a given earthquake; however, they are adequately correlated with the earthquake magnitude.

Building Behavior Factor q_s

In addition to the development of IDRS and ductility-dependent behavior factors of SDOF systems, considerable interest has been given to the evaluation of the available behavior factor supplied by entire structural systems (q_s) following different performance criteria, also compared to the behavior factor specified by modern building codes for design (q_d) following allowable stress, ULS, or PBD design procedures. Such studies have been specifically related to typical RC or steel building construction, either modern designs according to a particular seismic design code or existing structures, designed using past regulations. The purpose of such studies aimed for the evaluation, calibration, or reliability analysis (often using stochastic analysis procedures) of the behavior factor(s) specified by the subject

Behavior Factor and Ductility, Fig. 5 Evaluation of the overstrength, the ductility, and the behavior factor of an existing RC structure (From Repapis et al. 2006a)

code or structural system under scrutiny. Although most studies (especially related to code design parameter calibration and reliability analysis) have been aimed toward the evaluation of the overall design behavior factor q_s , studies of specific structural systems (e.g., RC shear wall or steel braced frame structures) have also been concerned with the evaluation of the behavior factor due to overstrength q_Ω .

Generally, the evaluation of q_s of a new or an existing structure is based on either static push-over (SPO) or time history inelastic analyses under an earthquake excitation set. The resulting q is particular to the building type and structural material under scrutiny, the EDRS, and the performance level criteria adopted, as well as the entire set of underlying code-specific design requirements inherent in the seismic design of the structure. Such requirements include, among others, the design load level during earthquake, the relative magnitude of gravity and seismic loads under the seismic load combination, limiting section geometry or reinforcement requirements, the degree of conservatism in the design, the code prescribed detailing rules, and so on. Hence, these behavior factors can only be

used for the corresponding design environment over which they have been calibrated for.

Evaluation of the Behavior Factor Using SPO Analysis

The evaluation of q_s using SPO methods involves the estimation of the capacity curve of the structure under a prescribed lateral load and/or displacement profile (modal, triangular, constant, adaptive) and crucial modeling assumptions (among others) of the strength and stiffness dependence of the member characteristics (also the finite element formulation itself), of the foundation and the joint models, including or not the second-order effects at the global and local element level. Following the definition of a set of local and global failure criteria (the damage indices), the available global ductility of the structural model is evaluated at the minimum roof deformation at incipient satisfaction of any of these indices, over the onset of yield roof deformation. Repapis et al. (2006a) have adopted SPO procedures in order to evaluate the available q_s and also q_Ω of existing RC plane irregular frames, typical of structural designs between the 1960s and 1990s in Greece (Fig. 5). Their results were

compared to dynamic analysis estimates of q_s , as described in the next section.

Evaluation of the Behavior Factor Using Dynamic Analysis

Several analytical estimations of q_s based on dynamic analysis have been published, in order to calibrate or verify the reliability of the behavior factor as a static analysis parameter in force-based seismic design, against local or global damage predictions. Two methods, the direct and the indirect method, have been proposed for evaluating q_s of a building using dynamic analysis (EC8 ENV 1988). Recently, in FEMA P-695 (2009), the procedure is formalized for a uniform reliability of evaluating q_s and q_Ω in PBD.

- (a) **Indirect evaluation of q_s .** A building initially designed for a given EDRS (shape, PGA equal to A_d , critical damping, and a design behavior factor q_d) is analyzed in the time domain under a base excitation whose response spectrum matches the EDRS entirely or locally in the vicinity of the initial period of the structure for the same critical damping. The PGA is linearly increased until incipient violation of any of a set of failure criteria, at the nominal collapse value of A_c . The behavior factor q_s is equal to

$$q_s = q_d \cdot \frac{A_c}{A_d} \quad (16)$$

The process is repeated for different earthquake input sets, and a statistical estimate of q_s is established for this type of building, design procedure, and performance criteria. The method suffers from the drawback that the performance indices do not depend linearly on the PGA (Kappos 1991); however, it has been commonly used since q_s is obtained at the expense of only one initial structural design and model formulation. This method falls closely with the application of the incremental dynamic analysis method (IDA) proposed by Vamvatsikos and Cornell (2003) for evaluating existing structural systems.

- (b) **Direct evaluation of q_s .** A set of collapse criteria is adopted together with an EDRS (shape, PGA, and damping) and a set of base excitation records matching the specific EDRS. The structure is designed for the assumed EDRS in a repetitive manner, initially assuming a design q_d as proposed by the code and, subsequently, for increasing (or possibly decreasing) values of q_d^i for each i_{th} design iteration; decreasing values may need to be considered in irregular or non-ductile structures in regions of high seismicity. For each i_{th} design, an inelastic model of the structure is formulated and analyzed over the design earthquake set. This design – analysis procedure – is repeated until any of the preset collapse criteria is incipiently violated: this limiting q_d^i is the behavior factor q_s .

$$q_s = \max(\text{or min}) q_d^i \quad (17)$$

In this case, a direct redesign method is adopted for q_s at the expense of several structural (re)designs. As before, the resulting behavior factor is a function of the design assumptions as well as the performance level evaluation criteria and the design record set.

Kappos (1991) applied the direct method for the evaluation of q_s for two typical RC plane frames, namely, a moment frame and a dual frame-wall system, designed according to EC8 ENV (1988) for medium ductility class using a q_d of 3.50 and 2.10, respectively. Using performance limits of total and interstory drift, member shear capacity, and local curvature ductility μ_{φ} , the resulting available q_s were evaluated to be 4.9 and 3.4 of the bare frame and the dual system, respectively. Different criteria governed for each structure and base excitation: for the bare frame system, the story drift limit governed, while for the dual system, member failure governed the response (the ground story columns). Zeris et al. (1992) applied the direct method to medium-height RC frames with a relatively taller ground story designed according to EC8 ENV (1988) for ductility class II and a q_d of 3.50, observing design code limitations (e.g., member

Behavior Factor and Ductility, Fig. 6 Variation of the structural behavior factor q_s of a tall first-story building with base excitation amplitude (Zeris et al. 1992)

Behavior Factor and Ductility, Table 2 Comparison of building q_s using static and dynamic analysis for three excitations (minimum value, mean, and standard deviation) (Zeris et al. 2005)

Conforming ordinary frame, Zone I	5.44	6.78	5.22	1.84

geometry, reinforcement detailing). Adopting failure limits in interstory drift and μ_φ as a function of confinement, it was shown that for a μ_φ of 5 and 10, the q_s of the regular RC frame was 4.4 and 7.1, while the tall first-story frame was marginally able to satisfy the μ_φ limit of 5.0 at $q_s = q_d = 3.5$, supplying a $q_s = 4.6$ for $\mu_\varphi = 10$ (Fig. 6).

For the case of modern building designs, Kappos (1999) and Borzi and Elnashai (2000) evaluated the ductility and q_s of typical low- to medium-rise RC buildings designed according to the CEB model seismic code or EC8, using both SPO and dynamic analysis SPO. In addition to comparisons of SDOF q_μ predictions of their record datasets with those available in the literature (e.g., by Miranda and Bertero 1994), the problems associated with comparing q_μ of entire structural systems (after excluding q_Ω) with

SDOF analysis were considered in detail. The studies concluded that the design behavior factor in EC8 was conservative for the cases considered, although their results were conflicting (proving the fact that the design and building bias affects the end result), attributing the conservatism of q_s to either the structural overstrength or the ductility supply or both.

In order to establish q_s of typical existing irregular buildings in Greece constructed in the 1960s and 1970s, Zeris et al. (2005) applied IDA analysis methods for evaluating q_s using the indirect method of evaluation; these values were compared with values obtained from SPO analysis by Repapis et al. (2006b), taking into account both interstory drift and local critical region rotational ductility limits comparable to the previous study. The resulting estimates are compared in Table 2, showing that (i) the available behavior

factors are well below currently adopted and (ii) dynamic analysis predictions of q_s for irregular buildings tend to be more conservative than those using dynamic analysis, being closer to the minimum predictions obtained in the latter case.

Chryssanthopoulos et al. (2000) evaluated the reliability of the design behavior factor q_d adopted by the Eurocode for the case of a regular ten-story RC frame designed for ductility class M. Using the indirect method of evaluation of the available q_s , they assumed a statistical variation of the structural material properties (concrete and steel yield strength and ultimate failure strain of the reinforcement), the uncertainty in confinement (and therefore supplied μ_φ in the critical regions), and a set of spectrum compatible base excitation records, in order to evaluate the reliability of ULS design following EC8 recommendations for the subject building. At the same time, they established the variation of the available q_s of the subject frame under the base input set. They concluded that for a seismic hazard model with a return period of 475 years for Southern Europe, the violation of the initial design value (q_d) of 3.75 was to be expected in 0.6 % of the frames exhibiting this type of building and design characteristics and the material property variability assumed.

Summary and Conclusions

It should be noted at the outset that such an intentional underdesign approach (i.e., using a behavior factor) is by no means a socially irresponsible approach from the point of view of the engineers' role to the society. It is well accepted that economic limitations and design feasibility will define the intensity level that is socially acceptable for the design of structures for the extreme earthquake; furthermore, it is well known that the gradual increase of records through more dense earthquake monitoring grids of digital instruments has proven more and more often that the actual seismic load intensity at a site will surprise us, when an extreme

earthquake event happens. Consequently, until sufficient seismic data are available, structures will continue to be constructed in regions in which, historically or otherwise, a fault was not known to exist or the existing faults' ability to induce a given seismic magnitude has been underestimated. Such famous examples, among others, were (i) the unexpected 1983 Coalinga earthquake in a quiet region in California; (ii) the 1971 Sylmar earthquake with its surprising (*at the time*) Pacoima Dam record exceeding 1.0 g; (iii) the numerous strong motion records since then that have well exceeded 1.0 g in Chile, New Zealand, Taiwan, and elsewhere; and (iv) for Greece, the 1999 Athens earthquake that ruptured an unknown extension of a known fault in a low- to medium-seismicity zone with a design effective PGA of 0.16 g, yielding estimated PGAs of 0.5 g, and the 2014 earthquakes in a well-known seismically active region in Kefallinia, exceeding the design effective PGA by as high as 200 %. Such consistent overshoots of our impression of the expected level of shaking in a seismically affected region demonstrate the need for introducing to our designs reasonable reduction factors coupled with excess ductility capacity and structural redundancy, rather than adopting $q_d = 1.0$ -type designs with no built-in ductility.

Extensive statistical studies have demonstrated that the q (or R) factors of SDOF systems are not sensitive to the earthquake magnitude unless near the causative fault, while they show a reasonable similarity (in terms of the estimated q_μ - μ - T relations) between earthquake faults of similar tectonic characteristics. Furthermore, they do not seem to be sensitive to the hysteretic shape of the system, for EPP and hardening systems of conventional new buildings. They are sensitive, however, to softening cyclic response, such as the case of structures with excessively softening or brittle failure mechanisms, such as existing RC frame or frame-wall structures, buildings with strong P - δ effects, or infilled RC frames with weak infills. They also depend strongly on the EDRS (de)amplification in the case of a resonant (or not) structural period near

the predominant period of the local soil conditions, in soft soil sites. These observations make the specification in earlier codes of constant system-dependent q_μ for design unconservative.

Can the behavior factor q_μ be increased to 1.0 (elastic response) at the gain of lack of implementing ductility into the system (i.e., $q_s = q_\Omega$)? Although the incorporation of ductility was initially imperative in seismic designs, this is no longer the case, and the codes are coming at the end of closed circle situation at this point, where one may (at the national level) relax this compulsory requirement. In this context, EC8 (2004), for instance, accounts for the case of a low ductility class (DCL) design, whereby a contemporary seismic design may for all practical purposes ignore all seismic detailing provisions for ductility, provided that a q_d close to 1.0–1.50 is adopted; in fact, the New Greek Code for Concrete Works still in effect in parallel usage with EC8 (2004) during the publication of this work allows for such a non-ductile design, even though the Greek National Annex of EC8 (2004) wisely, in the authors' opinion, precludes the use of DCL buildings in Greece. Given the performance of non-ductile structures in strong earthquakes and the possibly increased cost of introducing ductility detailing into the structure, it is believed that the practice of neglecting to incorporate ductility may lead to unsafe designs; therefore, adequate behavior factors with ductile detailing should be introduced, so that incorporating ductility is financially feasible.

Introduction

Traditional model-based structural modal analysis and damage identification methods are typically parametric and user involved; as such, they are usually associated with demanding computational resources and require quite a lot of prior knowledge of structures. For practical

applications, it would be useful to seek efficient structural identification methods that may be able to extract the salient information directly from the measured structural signals. The recently widely deployed advanced structural health monitoring (SHM) systems in structures with dense sensors also support such an effort: the massive recorded data especially call for efficient data-driven algorithms (Yang and Nagarajaiah 2014c, d) for further structural assessment.

Recently, blind source separation (BSS) has emerged as a new unsupervised machine learning tool (Hyvärinen and Oja 2000) and has been extensively studied in structural dynamics and output-only modal identification (Antoni 2005; Kerschen et al. 2007; Yang and Nagarajaiah 2013a, b, c, 2014a, b; Poncelet et al. 2007; Zhou and Chelidze 2007; McNeill and Zimmerman 2008; Hazra et al. 2010; Hazra and Narasimhan 2010; Sadhu et al. 2011, 2012; Abazarsa et al. 2013; Antoni and Chuahan 2013; Ghahari et al. 2013). Essentially, BSS techniques are able to recover the hidden source signals and their underlying factors using only the observed mixtures; it is thus suitable to perform output-only structural identification when structural input or excitation is usually extremely difficult or expensive to obtain.

This entry presents the authors' recent work on data-driven output-only modal identification and damage detection of structures. It is found that exploiting the sparse essences of modal expansion and damage information can efficiently and effectively address some challenging problems in output-only modal identification and damage detection via BSS. A series of novel algorithms are developed with experimental and real-world structure examples for demonstrations.

Blind Identification of Damage via Sparse Independent Component Analysis (ICA)

The sparse damage features hidden in the structural information can be blindly extracted via a

BSS technique called independent component analysis (ICA), as detailed in the following.

ICA is popularly used to estimate the blind source separation (BSS) model (Hyvärinen and Oja 2000),

$$\mathbf{x}(t) = \mathbf{A}\mathbf{s}(t) = \sum_{i=1}^n \mathbf{a}_i s_i(t) \quad (1)$$

using only the observed mixture vector $\mathbf{x}(t) = [x_1(t), x_2(t), \dots, x_m(t)]^T$; $\mathbf{s}(t) = [s_1(t), s_2(t), \dots, s_n(t)]^T$ and $\mathbf{A}$ denote the latent source vector and the unknown constant $m \times n$ linear mixing matrix, respectively, to be simultaneously estimated. $\mathbf{a}_i$ is the i th column of $\mathbf{A}$ and is associated with the corresponding source $s_i(t)$. The assumption of $m = n$ is imposed herein, i.e., the number of mixtures equals that of the sources and $\mathbf{A}$ is square. With only $\mathbf{x}(t)$ known, Eq. 1 may not be mathematically solved by classical methods; additional assumption is thus needed to estimate the BSS model.

The principle of ICA estimation is based on the classical central limit theorem (CLT), which states that a sum of independent random variables tends to distribute toward Gaussian, i.e., a mixture of independent random variables is always more Gaussian than any one of the original variables (except that the mixture only contains one random variable). As seen in Eq. 1, mixtures are expressed as a weighted sum of the sources themselves; they are thus always more or equally Gaussian than the sources. ICA therefore searches for proper demixing matrix $\mathbf{W}$ such that the recovered independent components (ICs) $\mathbf{y}(t) = [y_1(t), y_2(t), \dots, y_n(t)]^T$ obtained by

$$\mathbf{y}(t) = \mathbf{W}\mathbf{x}(t) \quad (2)$$

are as non-Gaussian as possible and thus approximate $\mathbf{s}(t)$. Each IC $y_i(t)$ is computed by

$$y_i(t) = \mathbf{w}_i \mathbf{x}(t) \quad (3)$$

with $\mathbf{w}_i$ denoting the i th row of $\mathbf{W}$. By seeking those ICs which maximize non-Gaussianity, the

sources (and simultaneously the mixing matrix) can therefore be recovered by ICA.

Non-Gaussianity of a random variable can be measured by some contrast function, e.g., negentropy. The entropy of a discrete random variable $v = \{v^1, v^2, \dots, v^i, \dots\}$ is defined by

$$H(v) = -\sum_i p(v = v^i) \cdot \log p(v = v^i) \quad (4)$$

where $p(\cdot)$ is the probability mass operator. Entropy measures the uncertainty or randomness of a random variable. For example, for a random variable with impulse probability mass function, its entropy is zero, i.e., it is completely determined.

The Gaussian random variable has the largest entropy among all other random variables with equal variance (Hyvärinen and Oja 2000), i.e., it is the most random or uncertain one. On the other hand, a random variable with sparse representation has small entropy as it is less random or easier to be predicted. This conclusion yields the definition of negentropy as a measure of non-Gaussianity given by

$$J(v) = H(v_{\text{gau}}) - H(v) \quad (5)$$

in which v_{gau} is a standardized Gaussian random variable (zero mean and unit variance); it quantitatively evaluates the entropy distance of a (standardized) random variable from a Gaussian variable. Finding the ICs that maximize the negentropy by ICA thus yields random variables with sparse representation (Yang and Nagarajaiah 2014a). This finding turns out very useful for damage identification, as subsequently described.

A simplified approximation to the negentropy is the classical kurtosis, which is defined by

$$\text{kurt}(v) = E[v^4] - 3(E[v^2])^2 \quad (6)$$

where $E[\cdot]$ denotes the expectation operator. The kurtosis of a Gaussian random variable is zero, and that of a non-Gaussian random variable is nonzero. It is easy to estimate and computationally efficient. The FastICA is one of the most

efficient algorithms implementing ICA estimation and is adopted in this study.

Damage may behave as pulse-like information hidden in the structural vibration response signals once they are processed further such as in the wavelet domain. The pulse-like feature containing damage information may be buried in the noisy wavelet-domain signals on a certain scale. Because ICA biases to extract sparse components from the observations, feed the wavelet-domain responses $\mathbf{x}^l(t)$ at the l th scale as mixtures into the BSS model,

$$\mathbf{x}^l(t) = \mathbf{A}\mathbf{s}(t) \quad (7)$$

If there is any pulse-like feature hidden in $\mathbf{x}^l(t)$, then ICA will extract it, which is to be revealed in the recovered sparse component $y_j(t)$ with sharp spikes indicating damage

$$\mathbf{y}(t) = \mathbf{W}\mathbf{x}^l(t) \quad (8)$$

Such $y_j(t)$ is proposed as the “interesting” source within the damage identification framework. Note that $\mathbf{x}^l(t)$ inherits the temporal information of the responses; this implies that the recovered “interesting” source $y_j(t)$ retains temporal signatures of the inflicted damage, which is indicated by the time instant location of the sharp spike.

Expanding the WT-BSS model Eq. 7 as

$$\begin{aligned} \mathbf{x}^l(t) &= \sum_{i=1}^n \mathbf{a}_i s_i(t) \\ x_1^l &= \sum_{i=1}^n a_{1i} s_i(t) = a_{11} s_1(t) + a_{12} s_2(t) + \dots + a_{1n} s_n(t) \\ x_j^l &= \sum_{i=1}^n a_{ji} s_i(t) = a_{j1} s_1(t) + a_{j2} s_2(t) + \dots + a_{jn} s_n(t) \\ x_n^l &= \sum_{i=1}^n a_{ni} s_i(t) = a_{n1} s_1(t) + a_{n2} s_2(t) + \dots + a_{nn} s_n(t) \end{aligned} \quad (9)$$

Observe that the mixing coefficient a_{ji} locates the mixture and the source by its indices j and i , respectively, and the columnwise vector $\mathbf{a}_i = [a_{1i}, a_{2i}, \dots, a_{ji}, \dots, a_{ni}]^T$ contains the spatial signature of the corresponding source $s_i(t)$. Herein, $\mathbf{a}_i$ and its element a_{ji} are proposed as the

Blind Identification of Output-Only Systems and Structural Damage via Sparse Representations, Fig. 1 Sparse ICA simultaneous identification of both structural damage instant and damage location: (a) the

experimental structure with four sensors embedded subject to white noise excitation at the base and (b) the WT-ICA identification results

source distribution vector (SDV) and source distribution factor (SDF), respectively; they describe how source $s_i(t)$ is distributed among n mixtures. Specifically, if a_{ji} has the largest (absolute) value among $\mathbf{a}_i = [a_{1i}, a_{2i}, \dots, a_{ji}, \dots, a_{ni}]^T$, then $x_j(t)$ contains most $s_i(t)$ components among all the mixtures (Yang and Nagarajaiah 2014a).

The proposed concepts of SDV and SDF are readily extended to damage localization issues. As the structural response in the vicinity of damage naturally contains most spike-like features, damage can be localized by tracking the spike in the SDV of the recovered impulse-like IC, which is the “interesting” source. Figure 1 shows an experimental structure application of WT-ICA

in simultaneous identification of both damage instant (at the 10th second) and damage location (the second sensor, left column in the first floor) by the spike feature in the recovered “interesting” source and the corresponding spatial signature, respectively; the detail of this experiment is referred to Yang and Nagarajaiah (2014a).

Output-Only Modal Identification by Sparse Time-Frequency ICA

In the above section, the sparse wavelet ICA is introduced for identification of the hidden spike-like features that typically indicate structural damage information. In the following, the sparse properties of modal expansion are further exploited and lead to a new output-only modal identification method STFT-ICA within the BSS framework which can handle even highly damped structures, as detailed in the following.

For a linear time-invariant system with n degrees-of-freedom (DOF), the governing equation of motion is

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = \mathbf{f}(t) \quad (10)$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are the symmetric mass, (diagonalizable) damping, and stiffness matrices, respectively, and $\mathbf{f}(t)$ is the external force.

The system responses $\mathbf{x}(t) = [x_1(t), \dots, x_n(t)]^T$ can be expressed using the modal expansion

$$\mathbf{x}(t) = \Phi \mathbf{q}(t) = \sum_{i=1}^n \varphi_i q_i(t) \quad (11)$$

where $\Phi \in \mathbb{R}^{n \times n}$ denotes the inherent vibration mode matrix (real-valued normal modes) with its i th column (modeshape), and $\varphi_i \in \mathbb{R}^n$ is the modal response (real-valued).

The output-only identification issue pursues to identify the modal parameters by solely relying on the knowledge of $\mathbf{x}(t)$ without any excitation or input information to the system, such like identification of both Φ and $\mathbf{q}(t)$ only from $\mathbf{x}(t)$ in Eq. 11. Such is an ill-posed problem and may

not be solved mathematically. Traditional output-only modal identification methods usually presume a parametric model (e.g., a stochastic state space model) to proceed with the identification; however, they have a serious drawback of the model order determination problem. Other methods may suffer from sensitivity to noise, dependence on expert experience, and heavy computational burden. The BSS technique provides a straightforward and efficient algorithm for output-only modal identification, as detailed in the following.

The BSS problem has a similar pursuit with the output-only modal identification issue. The close similarity is implied between the modal expansion Eq. 11 and the BSS model Eq. 1. If the system responses are fed as mixtures into the BSS model, then the target of output-only identifying Φ and $\mathbf{q}(t)$ in Eq. 11 can be solved by blind recovery of $\mathbf{A}$ and $\mathbf{s}(t)$ using those BSS techniques dependent on the independence assumption since $\mathbf{q}(t)$ typically with incommensurable frequencies are independent on the modal coordinates.

It has been shown, however, that such direct extraction of time-domain modal responses by ICA has failed for higher-damped structures (only within 1 %) (Kerschen et al. 2007; Yang and Nagarajaiah 2013a, b, 2014a, Brewick and Smyth 2015). The primary reason lies in that ICA ignores the temporal information of signals, while the targeted modal responses possess significant time structure – exponentially decaying monotone sinusoids.

To address the aforementioned issues of ICA, it is proposed by Yang and Nagarajaiah (2013a) to transform the time-domain modal expansion Eq. 11 to the time-frequency domain where the target modal responses have sparse representations, using the short-time Fourier transform (STFT) prior to the ICA estimation,

$$\mathbf{X}_{f\tau} = \Phi \mathbf{Q}_{f\tau} = \sum_{i=1}^n \varphi_i Q_{f\tau,i} \quad (12)$$

where f and τ are the frequency and window indices, respectively. ICA then extracts the most

independent (sparse) components that are the time-frequency representation of the modal responses,

$$\tilde{\mathbf{Q}}_{f\tau} = \tilde{\mathbf{W}}\mathbf{X}_{f\tau} \quad (13)$$

The recovered independent sources $\tilde{\mathbf{Q}}_{f\tau} = [\tilde{Q}_{1,f\tau}, \dots, \tilde{Q}_{n,f\tau}]^T$ are supposed to be as sparse as possible and approximate the targeted sparse time-frequency representations of the monotone modal responses. The obtained mixing matrix is therefore the estimated normal mode, i.e., $\tilde{\Phi} = \tilde{\mathbf{A}} = \tilde{\mathbf{W}}^{-1}$. Once the normal modes are estimated, the time-domain modal responses can be recovered using the demixing matrix

$$\tilde{\mathbf{q}}(t) = \tilde{\mathbf{W}}\mathbf{x}(t) \quad (14)$$

whereby readily estimating the modal frequencies and damping ratios in free vibration are readily estimated by Fourier transform (FT) and Hilbert transform (HT) or logarithm-decrement technique (LT) (Nagarajaiah and Basu 2009; Basu et al. 2008; Nagarajaiah and Li 2004; Dharap et al. 2006; Koh et al. 2005a, b; Li et al. 2007).

Figures 2, 3, 4, and 5 as well as Tables 1 and 2 present the successful application of STFT-ICA in identification of the modal parameters of an experimental structure (Fig. 2) and a real-world structure subject to the Northridge Earthquake 1994 (Nagarajaiah and Dharap 2003; Nagarajaiah and Sun 2000, 2001), both of which are highly damped. The details are referred to Yang and Nagarajaiah (2013a).

Complexity Pursuit on “Independent” Modal Coordinates

Exploiting the properties of the system responses and modal responses can lead to an efficient output-only modal identification method (Yang and Nagarajaiah 2013b) that enjoys even wider success based on a new BSS learning rule complexity pursuit (Stone 2001), which states that the complexity of any mixture signal

Blind Identification of Output-Only Systems and Structural Damage via Sparse Representations, Fig. 2 The experimental highly-damped 3-story steel frame and the zoomed fluid damper

(system response) always lies between that of the simplest source (simplest modal response) and most complicated source (most complex modal response).

In statistics, the complexity of a signal, say, $y_i = \mathbf{w}_i\mathbf{x}$ (the temporal index is made implicit), is rigorously measured by Kolmogorov complexity. Given that Kolmogorov complexity is not intuitive and difficult to approximate in practice, Stone (2001, 2004) provided a simple yet robust complexity measure of a signal, temporal predictability, which is defined by

$$F(y_i) = \log \frac{V(y_i)}{U(y_i)} = \log \frac{\sum_{t=1}^N (\bar{y}_i(t) - y_i(t))^2}{\sum_{t=1}^N (\hat{y}_i(t) - y_i(t))^2} \quad (15)$$

where the long-term predictor $\bar{y}_i(t)$ and short-term predictor $\hat{y}_i(t)$ are given, respectively, by

Blind Identification of Output-Only Systems and Structural Damage via Sparse Representations,

Fig. 3 (a) System responses (free vibration) of the experimental structure (b) the recovered modal responses by STFT-ICA

$$\begin{aligned}\bar{y}_i(t) &= \lambda_L \bar{y}_i(t-1) + (1 - \lambda_L) y_i(t-1) \quad 0 \leq \lambda_L \leq 1 \\ \hat{y}_i(t) &= \lambda_S \hat{y}_i(t-1) + (1 - \lambda_S) y_i(t-1) \quad 0 \leq \lambda_S \leq 1\end{aligned}\quad (16)$$

The parameter λ is defined by the half-life parameter h as

$$\lambda = 2^{-1/h} \quad (17)$$

where $h_S = 1$ and h_L is arbitrarily set (say, 900,000) as long as $h_L \gg h_S$ (Stone 2001, 2004).

Fig. 4 Sensor outline of the highly-damped USC hospital building

$$F(y_i) = F(\mathbf{w}_i, \mathbf{x}) = \log \frac{V(\mathbf{w}_i, \mathbf{x})}{(\mathbf{w}_i, \mathbf{x})} = \log \frac{\mathbf{w}_i \bar{\mathbf{R}} \mathbf{w}_i^T}{\mathbf{w}_i \hat{\mathbf{R}} \mathbf{w}_i^T} \quad (18)$$

where $\bar{\mathbf{R}}$ and $\hat{\mathbf{R}}$ are the $n \times n$ long-term and short-term covariance matrix between the mixtures, respectively; their elements are defined as

$$\begin{aligned} \bar{r}_{ij} &= \sum_{t=1}^N (x_i(t) - \bar{x}_i(t)) (x_j(t) - \bar{x}_j(t)) \\ \hat{r}_{ij} &= \sum_{t=1}^N (x_i(t) - \hat{x}_i(t)) (x_j(t) - \hat{x}_j(t)) \end{aligned} \quad (19)$$

Therefore, given a set of mixtures $\mathbf{x}(t)$, the CP learning rule is formulated to search for the demixing vector $\mathbf{w}_i$ which maximizes the temporal predictability contrast function $F(\cdot)$; this can

be solved by the classic gradient ascent technique as described in the following.

Following Eq. 18, the derivative of F with respect to $\mathbf{w}_i$ is

$$\nabla_{\mathbf{w}_i} F = \frac{2\mathbf{w}_i}{V_i} \bar{\mathbf{R}} - \frac{2\mathbf{w}_i}{U_i} \hat{\mathbf{R}} \quad (20)$$

By iteratively updating $\mathbf{w}_i$, a maximum of F is guaranteed to be found; the extracted component $y_i = \mathbf{w}_i \mathbf{x}$ with maximum temporal predictability is the least complex signal and thus approaches the simplest source hidden in the mixtures, according to Stone's theorem in the CP learning rule.

Restricted to Stone's theorem (Xie et al. 2005), however, the sources can only be extracted one by one by maximizing the temporal

Blind Identification of Output-Only Systems and Structural Damage via Sparse Representations,

Fig. 5 (a) System responses (during the Northridge Earthquake 1994) of the USC hospital building (b) the recovered modal responses by STFT-ICA

predictability using the gradient ascent technique. Stone (2001) proposed a more elegant algorithm that can efficiently extract all the hidden sources simultaneously, described as follows.

The gradient of F reaches zero in the solution, where

$$\nabla_{\mathbf{w}_i} F = \frac{2\mathbf{w}_i}{V_i} \bar{\mathbf{R}} - \frac{2\mathbf{w}_i}{U_i} \hat{\mathbf{R}} = 0 \quad (21)$$

Blind Identification of Output-Only Systems and Structural Damage via Sparse Representations,

Rewriting as

$$\mathbf{w}_i \bar{\mathbf{R}} = \frac{V_i}{U_i} \mathbf{w}_i \hat{\mathbf{R}} \quad (22)$$

yields a well-defined generalized eigenproblem (Stone 2001); the solution for $\mathbf{w}_i$ can thus be obtained as the eigenvector of the matrix $\hat{\mathbf{R}}^{-1} \bar{\mathbf{R}}$, with the eigenvalue $\gamma_i = V_i/U_i$. The sources can then be efficiently extracted simultaneously by

$$\mathbf{s}(t) = \mathbf{y}(t) = \mathbf{W} \mathbf{x}(t) \quad (23)$$

where the eigenvector matrix $\mathbf{W}$, with $\mathbf{w}_i$ as its i th row, is the target demixing matrix such that $\mathbf{A} = \mathbf{W}^{-1}$ and $\mathbf{y}(t) = [y_1(t), \dots, y_n(t)]^T$ is the recovered component vector which approaches the source vector $\mathbf{s}(t)$.

The aforementioned CP framework can then be cast into the modal identification whose physical interpretation is based on a new concept of “independent physical system on modal coordinates” (Yang and Nagarajaiah 2013b). The CP method is successful as shown in Figs. 6, 7, 8, and 9 and Tables 3 and 4 in identification of closely spaced couples with high-damped modes and in the presence of nonstationary seismic excitation.

Sparse Component Analysis of Modal Expansion

Existing BSS-based output-only modal identification methods may not be applied to the underdetermined problem where $m < n$ (i.e., only partial observations are available), which also often arises; e.g., for a large-scale structure, compared to its complexity with quite a few active modes, the measurement sensors may be limited. In this situation, the SCA method (Gribonval and Lesage 2006; Yang and Nagarajaiah 2013c) is used to tackle both the determined and underdetermined problem by exploiting the sparsity essence of the modal response. The targeted modal responses, which are viewed as sources in the BSS framework, are monotone, implying that they are active at only one distinct frequency, respectively. Therefore, they are most sparsely and disjointly distributed in the frequency domain and naturally satisfy the source sparsity assumption of SCA. Hence, transform the modal expansion Eq. 11 into the sparse frequency domain to incorporate modal identification to the SCA framework

$$\mathbf{x}(f) = \tilde{\Phi} \mathbf{q}(f) = \sum_{i=1}^n \varphi_i q_i(f) \quad (24)$$

with

$$\begin{aligned} \mathbf{x}(f) &= \mathcal{F}(\mathbf{x}(t)) = \int_{-\infty}^{\infty} \mathbf{x}(t) e^{-j2\pi f t} dt \\ \mathbf{q}(f) &= \mathcal{F}(\mathbf{q}(t)) = \int_{-\infty}^{\infty} \mathbf{q}(t) e^{-j2\pi f t} dt \end{aligned} \quad (25)$$

where $\mathcal{F}$, f , and j denote the Fourier transform operator, frequency index, and the imaginary operator, respectively. Note that $\mathcal{F}$ is an invertible linear transform; it holds the form of the modal expansion such that Eq. 24 is valid and Φ remains invariant.

To avoid complex elements in Eq. 24, it is more practical to use the cosine transform $\mathcal{F}^c$ (also linear) to yield real-valued $\mathbf{x}(f)$, simply replacing the Fourier basis $e^{-j2\pi f t}$ with the cosine

Blind Identification of Output-Only Systems and Structural Damage via Sparse Representations,

Fig. 6 (a) The system responses of a 3-DOF numerical model and (b) the modal responses recovered by CP in free vibration (closely-spaced coupled with high-damped modes)

basis $\cos 2\pi ft$ in Eq. 24. The DCT is adopted in the proposed SCA method, then $\mathbf{x}(f)$ and $\mathbf{q}(f)$ are understood as real-valued cosine transform coefficients.

Using the disjoint sparsity property of modal responses with distinct frequencies, at some f_k where only one modal response

$q_j(j = 1, \dots, n)$ is active and $q_i = 0$ for $i \neq j$, Eq. 24 becomes

$$\mathbf{x}(f_k) = \varphi_i q_j(f_k) \quad (26)$$

Therefore, the points of $\mathbf{x}(f)$ will cluster to the direction of the j th modeshape $\varphi_j(j = 1, \dots, n)$

Blind Identification of Output-Only Systems and Structural Damage via Sparse Representations, Fig. 7 (a) The experimental 3-story structure, (b) the modeshapes estimated by CP, and (c) the modeshapes estimated by SCA

such that the estimated vibration mode matrix $\tilde{\Phi}$ can be extracted by the automatic fuzzy C-means clustering algorithm.

For determined cases, $\tilde{\Phi}$ is square, and the time-domain modal responses can be recovered directly by

$$\tilde{\mathbf{q}}(t) = \tilde{\Phi}^{-1} \mathbf{x}(t) \quad (27)$$

from which the frequency and damping ratio can be estimated by straightforward Fourier transform and logarithm decrement, respectively. In underdetermined cases, $\tilde{\Phi}$ is rectangular. The frequency-domain modal sources $\tilde{\mathbf{q}}(f)$ can first be recovered using ℓ_1 -minimization (P_1): at each $f \in \Omega$,

$$\begin{aligned} \tilde{\mathbf{q}}(f) &= \arg \min \|\mathbf{q}(f)\|_{\ell_1} \quad \text{subject to} \quad \tilde{\Phi} \mathbf{q}(f) \\ &= \mathbf{x}(f) \end{aligned} \quad (28)$$

where $\|\mathbf{q}(f)\|_{\ell_1} = \sum_{i=1}^n |q_i(f)|$. The validity of this strategy resides in the ability of the ℓ_1 -minimization to recover the sparsest solution to Eq. 28, which is exactly the desired monotone frequency-domain modal responses since they are the sparsest solution among all feasible solutions to Eq. 28.

Using the inverse cosine transform, the time-domain modal responses can be readily recovered by

$$\tilde{\mathbf{q}}(t) = \mathcal{F}^{c-1}(\tilde{\mathbf{q}}(f)) \quad (29)$$

thereby estimating the frequency and damping ratio.

For demonstrations, Fig. 10 shows that SCA is able to recover the close modes coupled with high damping using only two sensors of the 3-DOF numerical model.

Bridge Foundations

Ayman A. Shama¹ and Hesham El Naggar²

¹Ammann & Whitney, New York, NY, USA

²Geotechnical Research Centre, Department of Civil and Environmental Engineering, The University of Western Ontario, London, ON, Canada

Introduction

The poor performance of bridges during the 1971 San Fernando earthquake has urged the engineering community to further investigate methods of analysis and evaluation of seismic loads and their effects on these structures. Later, earthquakes such as Northridge, 1994, and Kobe, 1995, have further increased engineers' awareness of the effects of earthquakes on bridges. The past two decades have witnessed a great evolution in seismic design codes, advance modeling, and analysis. Moreover, the importance of the interaction between the structure and the surrounding soil on the seismic response of bridge structures during earthquakes has been fully realized.

Past performance of foundations was satisfactory in moderate earthquakes and poor in large

earthquakes with magnitudes greater than seven. Examples include the 1964 M9.2 Alaskan Earthquake, the 1991 M7.6 Costa Rica Earthquake, the 1999 M7.8 Izmit-Turkey Earthquake, the 2010 M8.8 Chile Earthquake, the 2011 M9.0 Tohoku-Oki Earthquake in Japan, and the 2012 M7.4 Guatemala Earthquake. In all these earthquakes, spread footings failures were due to loss of bearing capacity and lateral spreading due to soil liquefaction. Figure 1 depicts photo of a collapsed bridge during the Limon Province, Costa Rica Earthquake. The piers have disappeared in the river a result of liquefaction and both bridge spans have collapsed during the earthquake.

The seismic response of bridge foundations depends on: the type, geometry, and embedment of the foundation; the characteristics of the surrounding soil; and the interaction between the foundation and the surrounding soil. Soil–structure interaction is the influence of the soil and structure both on each other simultaneously. Seismic ground motions that are not influenced by the presence of the structure are known as free-field motions. If the structure exists, the deformations of the foundations deviate from the deformations of the free-field motion and the dynamic response of the structure induces deformation of the supporting soil. The process in which the response of the soil influences the motion of the structure and the motion of the structure influences the response of the soil is known as soil–structure interaction (SSI). There are two approaches used to incorporate the effect of SSI in seismic analyses of structures, direct methods and simplified methods. In the direct approach, the entire soil–foundation–structure system is modeled and analyzed simultaneously in one step using finite element or finite difference methods with the seismic waves applied at the model boundaries. This approach requires specific programs that can idealize the nonlinear behavior of the soil and large CPU time for analysis. Although it is conceptually very attractive, it is fairly complex and very seldom been applied for practical bridge problems. Simplified methods include the substructure approach and the Winkler approach. The substructure approach includes subdividing the structure into two

Bridge Foundations,

Fig. 1 A bridge collapse
due to foundation failure
Costa Rica
Earthquake 1993

B

substructures, foundation and superstructure, with a convenient interface between the two. First, the stiffness and damping properties of the foundation system, for each degree of freedom, are first evaluated and then applied to the bridge superstructure in the form of springs and dashpots at the point of interface. The Winkler spring model (Winkler 1867) acts in conjunction with the foundation to eliminate rotational springs. The p-y curve method, which was developed for off-shore structures and used for analysis of deep foundations, originates from the Winkler spring method.

The most common types of bridge foundations are: (i) spread footings for sites of rock and stiff soil; (ii) pile-supported cap foundations for sites with soft soil or for sites with soil layers vulnerable to liquefaction; (iii) drilled shafts for cohesive soils, especially with deep groundwater or when construction of new foundations requires a small footprint wherein, a single drilled shaft under a single column can avoid the large footprint that would be necessary with a group of piles; and (iv) large gravity caissons for complex bridges such as cable supported bridges.

The subsequent sections of this chapter discuss the procedures for modeling bridge foundations for analysis including effects of SSL. Methods for designing these foundations to resist seismically induced forces and displacements are also explained.

Spread Footings

Spread footings are usually suitable for sites of rock and firm soils. The stability of these foundations under seismic loads can be evaluated using a pseudostatic bearing capacity procedure. The applied loads for this analysis can be taken directly from the results of a global dynamic response analysis of the bridge with the soil-foundation-interaction effects represented in the structural model.

Spread Footing Stiffness

A method to be selected for evaluating the foundation stiffness must adequately reflect the shape of the foundation–soil interface; the amount of embedment; the nature of the soil profile; and the mode of vibration and frequencies of excitation. The uncoupled spring approach satisfies all these conditions. It is accomplished through determining the dynamic impedance functions for the foundation. This method is adequate if the seismic foundation loads are not expected to exceed twice the ultimate foundation capacities. As illustrated in Fig. 2, the dynamic impedance model is an uncoupled single node model that represents the foundation element. An upper and lower bound approach to evaluating the foundation stiffness is often used because of the uncertainties in the soil properties and the static loads on the foundations. As a general rule of thumb, a factor

Bridge Foundations, Fig. 2 Analysis model for spread footings

of 4 is taken between the upper and lower bound (ATC-1995).

The dynamic impedance model is based on earlier studies on machine foundation vibrations, in which, it is assumed that the response of rigid foundations excited by harmonic external forces can be characterized by the impedance or dynamic stiffness matrix for the foundation. The impedance matrix depends on the frequency of excitation, the geometry of foundation and the properties of the underlying soil deposit.

The evaluation of the impedance functions for a foundation with an arbitrary shape has been solved mathematically using a mixed boundary-value problem approach or discrete variation problem approach. Currently, there are two commonly used approaches for evaluating the dynamic impedance functions for a shallow foundation. The first is based on the approximate solution for a circular footing rigidly connected to the surface of isotropic homogeneous elastic half space. The second approach is more general and is applicable to a foundation with an arbitrary shape.

In the equivalent circular base approach the impedance function of a foundation is obtained from the elastic solution of a rigid massless circular base resting on the surface of the soil for each degree of freedom independently. The impedance function for each degree of freedom is a frequency dependent complex expression, where its real part represents the elastic stiffness (spring constant) of the soil-foundation system and its imaginary part represents the damping in the soil-foundation system. The impedance function is expressed as:

$$\bar{k}_j = k_j(a_0, \nu) + i\omega c_j(a_0, \nu) \quad (1)$$

where, k_j is the real part represent the dynamic stiffness for a specific degree of freedom j , c_j is the imaginary part represent the damping for a degree of freedom j , ν is Poisson's ratio of the soil medium, a_0 is a dimensionless frequency expressed as:

$$a_0 = \frac{\omega r_j}{V_s} \quad (2)$$

in which, ω is the circular frequency of excitation in rad/s, r_j is equivalent radius for a specific degree of freedom, and V_s is the shear wave velocity of the soil medium. Both the dynamic stiffness k_j and the damping c_j are obtained in terms of the static stiffness K_j as:

$$k_j = \alpha_j K_j \text{ and } c_j = \beta_j \frac{K_j r_j}{V_s} \quad (3)$$

where α_j and β_j are dynamic modifiers are evaluated as function of the dimensionless frequency a_0 and Poisson's ratio ν .

Evaluation of the static stiffness coefficients can be obtained using the equivalent circular footing, wherein it is assumed that the footing is rigid and founded on top of a semi-infinite elastic half space. The rectangular footing is converted to an equivalent circular footing for each degree of freedom. The stiffness coefficients are evaluated for the circular footing and then multiplied

Bridge Foundations,
Fig. 3 Procedure for
evaluating equivalent
radius of a rectangular
footing

EQUIVALENT RADIUS:

TRANSLATIONAL:

$$R_o = \sqrt{\frac{4BL}{\pi}}$$

ROTATIONAL:

$$R_1 = \left[\frac{(2B)(2L)^3}{3\pi} \right]^{1/4} \qquad \text{(x-AXIS ROCKING)}$$
$$R_2 = \left[\frac{(2B)^3(2L)}{3\pi} \right]^{1/4} \qquad \text{(y-AXIS ROCKING)}$$
$$R_3 = \left[\frac{4BL(4B^2 + 4L^2)}{6\pi} \right]^{1/4} \qquad \text{(z-AXIS TORSION)}$$

by shape and embedment factors to obtain the solution for the rectangular base. The solution is carried out in five steps as follows:

Step 1: Determine the equivalent radius for each degree of freedom, which is the radius of a circular footing with the same area as the rectangular footing as shown in Fig. 3.

Step 2: Calculate the stiffness coefficients K_0 for the transformed circular footing (Table 1), where, G and ν in the table are the shear modulus and Poisson’s ratio for the soil-foundation system.

Bridge Foundations, Table 1 Static stiffness coefficients for a circular footing resting on the surface of soil

Displacement degree-of-freedom	k_0
Vertical translation	$\frac{4Gr}{1-\nu}$
Horizontal translation	$\frac{8Gr}{2-\nu}$
Torsional rotation	$\frac{16}{3}Gr^3$
Rocking rotation	$\frac{8Gr^3}{3(1-\nu)}$

Step 3: Multiply each of the stiffness coefficients values obtained in step 2 by the appropriate shape correction factor α from Fig. 4 (Lam and Martin 1986). This figure provides the shape

B

Bridge Foundations,
Fig. 4 Shape factors for
 rectangular footings (Lam
 and Martin 1986)

factors for different aspect ratios L/B for the foundation.

Step 4: Multiply the values obtained from step 3 by the embedment factor β using Fig. 5. D in these figures is the footing thickness.

Step 5: Calculate the dynamic stiffness and the damping coefficients using Eq. 3 and the charts displayed in Figs. 6, 7, and 8 (Veletsos and Verbic 1973),

The static stiffness can be calculated using the second approach for calculating the impedance functions for the soil-foundation system (Gazetas 1991). Using Fig. 9, a two-step calculation process is required. First, the stiffness terms are calculated for a foundation at the surface. Then, an embedment correction factor is calculated for each stiffness term. The stiffness of the embedded foundation is the product of these two terms. According to Gazetas, the height of effective sidewall contact, d , in Fig. 9 should be taken as the average height of the sidewall that is in good contact with the surrounding soil.

Considering the range of frequencies and amplitudes in earthquake ground motions compared to machine foundations, it is reasonable to ignore the frequency dependence of the stiffness as well as the damping parameters.

Based upon the results of the dynamic analysis, the peak dynamic loads and deformations of

the foundation are determined and compared to acceptable values. The foundation must be evaluated for bearing capacity and sliding resistance due to the seismic loads.

Seismic Design of Spread Footings

Earthquakes will induce moments and horizontal loads in addition to the traditional vertical loads applied to a spread footing. In low seismic hazard areas, spread footings may be proportioned to resist overturning, sliding, flexure, and shear due to forces obtained from the seismic analysis of the bridge. In high seismic regions, the flexural and shear demands are those associated with the over-strength plastic moment capacity of the column or pier attached to the footing. To represent the combined effect of the seismic forces and moments a resultant load that may have to be inclined and applied eccentrically can be applied in lieu of the seismic vertical forces, seismic horizontal forces, and seismic moments. Therefore, a procedure is established to account for load inclination and load eccentricity of footing through which the general bearing capacity equation of shallow footing is adjusted to account for these effects. This procedure is carried out in three steps as follows:

Step 1: Compute the seismic vertical loads, seismic horizontal loads, and seismic moments

Bridge Foundations,
Fig. 5 Embedment factors
for rectangular footings
(Lam and Martin 1986)

imposed to the footing. These seismic loads and moments can be taken directly from the results of a global dynamic response analysis of the structure with the soil–foundation interaction SFI effects represented in the structural model. For each direction, these forces are then combined into a single resultant force with an inclination angle β with respect to the vertical.

Step 2: Calculate the equivalent dimensions for the footing to account for the load eccentricity, which is caused by the seismic moments applied to the foundation in both directions. The vertical load can be transferred to an eccentric position defined by $e_b = M_b/Q$ and $e_l = M_l/Q$, where Q is the central vertical load due to seismic load plus other service loads;

M_b and M_l = seismic moments about the short and long axes of the footing; and e_b and e_l = eccentricities of the load Q about the centroid of the footing in the direction of the short and long axes respectively.

It is known from basic principles of strength of materials that if the eccentricity in one direction is less than 1/6 of the foundation's length in that direction, the footing is in compression throughout. As eccentricity exceeds this value, a loss of contact occurs. The concept of effective width was introduced by Meyerhof (1953) who proposed that at the ultimate bearing capacity of the foundation, it could be assumed that the contact pressure is identical to that for a centrally loaded foundation but of reduced width. The reduced

Bridge Foundations,**Fig. 6** Dynamic modifiers for vertically excited footing

dimensions as indicated in AASHTO-LRFD (AASHTO 2012) for a footing subjected to two-way eccentricity can be adopted as illustrated in Fig. 10.

Step 3: Adjust the static bearing capacity equation for inclination and eccentricity. Load inclination factors may be calculated as Vesic 1970 and added to the static bearing capacity equation to count for load inclination.

The sliding resistance of a spread footing should be evaluated independently of the bearing capacity, wherein, the unit adhesion and/or frictional resistance of the footing's base to sliding are multiplied by the area of the base to obtain the sliding resistance.

Spread footings are not allowed to be located in soils that are susceptible to liquefaction unless the footing is below the

maximum depth of liquefaction. Soil densifications or other acceptable methods for mitigating the potential for liquefaction may be used. Spread footings can be used in this case only if verification studies confirm that liquefaction potential has been mitigated.

Pile Footings

Pile footings generally consist of pile groups connected to a pile cap with pile diameters usually less than or equal to 24 in. They are preferred if the upper soil layers are weak or susceptible to liquefaction. Essentially, the seismic response of piles requires consideration of six degrees of freedom; that is, three translational components and three rotational components. The lateral soil

Bridge Foundations,
Fig. 7 Dynamic modifiers
for horizontally excited
footing

B

reactions are usually mobilized along the top 5–10 pile diameters. The axial soil resistances, however, develop at greater depths. Hence, the axial and lateral capacities of piles are considered to be uncoupled.

In general, seismic design of pile foundations is evaluated by the substructure method. First, the total structure is divided into two substructure models with a convenient interface between the two at the pile cap level. Next, the stiffness matrix of the pile group, which implies soil effects, is established using the foundation substructure model or simple methods. The stiffness matrix is then implemented in the superstructure model and seismic analysis is conducted using the superstructure model to determine the demands at the interface point. Finally, capacities of individual piles are evaluated and compared to the demands by back substitution in the substructure model. For a proper determination of the seismic

demand, it is imperative to estimate precisely the foundation stiffness to be included in the overall structural model for determination of the demands.

Pile Foundation Stiffness

Soils are inherently nonlinear, starting from incredibly small load levels. Lateral loads on piles are resisted by the surrounding soil. Therefore, piles exhibit nonlinear load deflection characteristics. This behavior is represented assuming the pile as a beam supported on Winkler springs that are characterized by nonlinear p-y curves for lateral loading, or t-z and q-z for vertical loading. These curves characterize the lateral soil resistance per unit length of pile as a function of the displacement. These relationships are generally developed on the basis of semiempirical curves, which reflect the nonlinear resistance of the local soil surrounding the pile at a certain depth.

Bridge Foundations,**Fig. 8** Dynamic modifiers for footing in rocking motion

The two most commonly used p-y models are those proposed by Matlock (1970) for soft clay and by Reese et al. (1974) for sand. The most commonly used t-z and q-z models are those developed by McVay et al. (1998).

There are two methods for modeling the behavior of pile groups for seismic response studies, the soil-pile stiffness as will be explained in the following subsections.

Coupled Pile Foundation Stiffness Matrix

In this method, a quasi-dynamic analysis for the pile group is conducted by applying loading (either as forces or displacements) at the interface node between the superstructure and foundation model using linearized properties for the soils. Linearized properties for a single pile can be achieved by assuming secant foundation stiffness

at 0.5–0.65 of peak deflection (Lam et al. 1998). A stiffness matrix can be obtained by prescribing a unit deformation vector for each degree of the six degrees of freedom, while keeping the other five degrees zero. The resultant force vector corresponding to each unit deformation vector can be used to form the corresponding column vector in the stiffness matrix. The stiffness matrix must be positive definite otherwise, numerical problems may be expected when the stiffness matrix is implemented in the overall structural model. One way to ensure that the stiffness matrix is positive definite is to invert it and check that the diagonal elements in the inverted (compliance) matrix are positive values. Programs such as LPILE (2010), FLPIER (Hoit and McVay 2010), and SWM (Ashour and Norris 2000) may be used to establish the foundation

Stiffness Parameter	Stiffness at Surface, K_i

stiffness matrix of the pile group through an iterative process.

Simplified Procedure for Pile Group Stiffness Matrix

The simplified method assumes coupling only between shear and overturning moment for the single pile. The general form of a single pile stiffness matrix can take the form:

$$\begin{bmatrix} K_{xx} & 0 & 0 & 0 & -K_{x\theta_y} & 0 \\ 0 & K_{yy} & 0 & K_{y\theta_x} & 0 & 0 \\ 0 & 0 & K_{zz} & 0 & 0 & 0 \\ 0 & K_{\theta_x y} & 0 & K_{\theta_x x} & 0 & 0 \\ -K_{\theta_y x} & 0 & 0 & 0 & K_{\theta_y y} & 0 \\ 0 & 0 & 0 & 0 & 0 & K_{\theta_z} \end{bmatrix} \quad (4)$$

in which, K_{xx} , K_{yy} are the lateral stiffnesses; K_{zz} is the axial stiffness; and $K_{x\theta_y}$ and $K_{y\theta_x}$ are corresponding coupled stiffnesses between shear and overturning moment.

The simplified method involves five basic steps (Lam et al. 1991) as follows:

1. Determine the stiffness coefficient of a single pile under lateral loading.
2. Determine the stiffness coefficient of a single pile under axial loading.
3. Superimpose the stiffness of individual piles to obtain the pile group stiffness.
4. Solve for the stiffness contribution of the pile cap.
5. Superimpose the stiffness of the pile cap to the pile group.

These steps are described herein.

Step 1: Single Pile Under Lateral Load Lam and Martin (1986) came to a realization that lateral load-deflection characteristics representing the overall stiffness of the soil pile system are dominated by the elastic pile stiffness over the nonlinear soil behavior. Moreover, the localized zone of influence is limited to the upper 5–10 pile diameters. Hence, they concluded that linear solutions may be adequate for pile stiffness evaluations. They developed single-layer, pile-head

stiffness design charts for lateral loading as presented in Figs. 11, 12, and 13. These charts are applicable for piles up to 24 in. Two parameters are required to define the soil-pile system: the pile bending stiffness, EI , and the coefficient of variation f of soil reaction modulus E_s with depth. The coefficient f has units of force/unit volume.

Step 2: Single Pile Under Axial Load The recommended LRFD guidelines for the seismic design of highway bridges proposed the following simple equation for the determination of the axial stiffness of the pile:

$$K_v = 1.25 \frac{E_p A}{L} \quad (5)$$

Wherein, E_p is the modulus of elasticity of pile material; A is cross sectional area of pile; and L is length of pile.

Step 3: Pile Group Stiffness The stiffness of the single pile can be used to establish the pile group stiffness matrix. If the pile group consists of vertical piles, the stiffness summation procedure is relatively straight forward. The stiffness for the translational displacement terms (the two horizontal and the vertical displacements) and the cross-coupling terms can be obtained by multiplying the corresponding stiffness components of an individual pile by the number of piles.

In general, the axial stiffness of the piles will dominate the rotational stiffness of the group. Therefore, the rotational stiffness terms require consideration of this additional stiffness component. Similarly, there is an interaction between the translational stiffness of piles and the torsional stiffness of the group. The following equation (Lam et al. 1991) can be used to develop the rotational terms of a pile group:

$$K_{RG} = NK_{RP} + \sum_{n=1}^N K_{\delta n} S_n^2 \quad (6)$$

In which, K_{RG} and K_{RP} are the rotational stiffness of the pile group and an individual pile respectively; N is the number of piles in the pile group;

Bridge Foundations,
Fig. 11 Pile translational
stiffness

$K_{\delta n}$ is the translational stiffness coefficient of an individual pile (axial for group rocking stiffness and lateral for group torsional stiffness); and S_n is the distance between the n th pile and the axis of rotation.

Step 4: Stiffness Contribution of the Pile Cap In addition to the component of soil resistance acting on piles, the passive pressure soil resistance on the vertical pile cap face can be added to the stiffness and resistance obtained from the pile members. This is contingent on stable level ground conditions. The pile cap stiffness can be estimated as the ultimate soil capacity divided by an estimated displacement to mobilize this capacity. Centrifuge tests (Gadre 1997) showed that the deflection level to reach the ultimate pile cap capacity occurs at about 0.02 times the embedment depth. This equivalent linear secant stiffness can be added to the stiffness of the piles.

Step 5: Superimpose the Stiffness of the Pile Cap to the Pile Group The resultant pile cap stiffness obtained from step 4 can be added to the diagonal lateral translational stiffness coefficients in the pile group stiffness matrix for the total pile group–pile cap stiffness matrix.

The above procedure does not account for group effects which relate to the influence of the adjacent piles in affecting the soil support characteristics. Full-scale tests by a number of investigators demonstrate that the lateral capacity of a pile in a pile group may be less than that of a single pile due to the interaction between closely spaced piles in the group (group efficiency). As the pile spacing reduced, the reduction in lateral capacity becomes more pronounced. In general, pile spacing of less than 3–5 pile diameters are necessary before the effects of pile interaction becomes significant in practical terms. Type and strength of soil, number of piles, and loading level are other factors that may affect the

Bridge Foundations,
Fig. 12 Pile rotational
 stiffness

efficiency and lateral stiffness of the pile. Moreover, in addition to group effect, gapping, and potential cyclic degradation were also subject of many investigations (e.g., Brown et al. 1987; McVay et al. 1995). It has been shown that a concept based on p -multiplier applied on the standard stiffness matrix can work reasonably to account for pile group and cyclic degradation effects.

Seismic Design of Pile Footings

Design of pile footings for seismic effects is often relatively a complex process. The strategy of the seismic design is to determine capacity and deflection of the piles under the action of the seismic lateral loads and ensure the integrity of the pile group against liquefaction.

Moment Capacity of Pile Groups

Typically, the foundation system is designed to be capacity protected, which ensures that damage occurs above ground, where it can be accessed and repaired. The seismic moment capacity of the

pile group will govern the design. For a fixed-head pile group, the piles must be designed for the plastic hinging moment capacity of the column/pier connected to the pile cap. The maximum negative moment occurs at the base of the pile cap while the maximum positive moments occur in the pile at a short depth below the base. In this regard, the pile cap has to be designed to behave rigidly. The rigid response of the footing may be assumed if the following equation is satisfied (AASHTO 2011):

$$\frac{L}{D} \leq 2.5 \quad (7)$$

where, L is the cantilever overhang length measured from the face of pier or column to the outside edge of the pile cap and D is the depth of the pile cap. Due to the interaction between the rocking response and the vertical response of a pile group, the axial demands on an individual pile can be estimated as:

Bridge Foundations,**Fig. 13** Pile cross-coupling stiffness

$$F = \frac{P}{N} \pm \frac{M_Y^{\text{col}} C_{X_i}}{I_{pgy}} \pm \frac{M_X^{\text{col}} C_{Y_i}}{I_{pgx}} \quad (8)$$

in which, P is the total axial load due to dead load, footing weight, and seismic load; N is the total number of piles in a group; C_{X_i} and C_{Y_i} are the distances from neutral axis of pile group to i th row of piles measured parallel to the x and y axes respectively; M_X^{col} and M_Y^{col} are the plastic moment capacities of the pier or column connected to the footing about the x and y axes respectively; and I_{pgx} and I_{pgy} are the effective moment of inertia of pile group about the x and y axes evaluated as:

$$I_{pgx} = \sum_{i=1}^{N_x} n_x c_{yi}^2 \quad \text{and} \quad I_{pgy} = \sum_{i=1}^{N_y} n_y c_{xi}^2 \quad (9)$$

where n_x and n_y are the number of piles in a single row parallel to the x and y axes.

For a foundation protected design strategy, the connection of pile to cap should be designed such that its moment capacity exceeds that of the pile.

Pile-to-Cap Connection

The moment capacity at the connection depends on both the depth of embedment of the pile into the cap and the reinforcement arrangement. Driven precast piles should be constructed with considerable spiral confining steel to ensure good shear strength and tolerance of yield curvatures that may be exerted during the seismic event. Parametric studies (Harris and Petrou 2001) with prestressed piles suggest that the embedment length should be taken as the larger of the pile diameter or 12 in.. Experimental studies (Shama and Mander 2004) have showed that an embedment of one pile diameter of a timber pile into a pile cap was sufficient to develop the full moment capacity of the pile and provide a ductile response. Experimental studies (Rollins and Stenlund 2011) also showed that steel pipe piles

Bridge Foundations,
Fig. 14 Drilled shafts
 configuration

embedded 24 in. into a pile cap can produce a sufficient moment capacity for the connection without the need for a reinforcement detail. These observations agree with the results of cyclic tests on steel HP piles (Shama et al. 2002).

Lateral Capacity of Pile Footings

The lateral capacity of piles requires compiling of both geotechnical and structural engineering principles. For a successful design, it is important to get the soil resistance mobilized before structural failure of the pile. The relative importance of the pile cap lateral capacity to the individual piles needs to be considered. Therefore, the lateral capacity evaluation must include the resistance developed by the pile cap in addition to the lateral shear resistance of the piles. Including the lateral capacity of the pile cap is contingent upon efficient compaction of the soils around the pile cap to improve the cap resistance. The lateral capacity of the pile cap must include the passive pressure mobilized at the front face of the cap perpendicular to the seismic load and the interface shear resistance developed along the sides of the cap parallel to the application of the seismic load.

Drilled Shafts

Drilled shafts are large diameter piles that are designed to sustain high axial loads and overturning moments. They are constructed

using drilling (excavating) equipment capable of auguring or coring 30" to 120" diameter excavations into soil and rock. After the excavation is completed, a reinforcing cage is placed in the excavation and the excavation is filled with high slump concrete. Drilled shafts are usually constructed with steel shells.

Drilled shafts are attached to the superstructure in two configurations as illustrated in Fig. 14. In the first configuration a group of drilled shafts, usually 4–6 are connected to a cap that supports the bridge pier or column. In the second configuration, a large diameter shaft is extended as a structural unit to support the bridge superstructure. The second configuration comes in two alternatives as illustrated in Fig. 15 (Priestley et al. 1996). In the first alternative, the section of the column above the ground is similar to that of the shaft. The maximum moment forms at a depth of typically 1.5–2.5 shaft diameter. A disadvantage of this alternative is that the extent of damage to the plastic hinge region will be below ground after an earthquake and needs excavation of the soil material for inspection. With the alternative detail of Fig. 15b, the moment capacity of the shaft below ground is increased above that of the column above ground to ensure that hinging occurs at the base of the column and damage can be expected after an earthquake. The disadvantage of this detail is that it is more expensive with respect to the alternative of Fig. 15a.

Bridge Foundations, Fig. 15 Extended shaft seismic design alternatives (Priestley et al. 1996)

Stiffness of Drilled Shaft Foundations

The most common methods for modeling drilled shaft behavior in a global bridge model for seismic response analysis are categorized to three classes:

- Beam supported on nonlinear Winkler springs
- Equivalent cantilever model
- Coupled foundation stiffness matrix

Beam Supported on Nonlinear Winkler Model

The beam supported on nonlinear Winkler springs method can be implemented in the structural model without any difficulty as the number of large diameter drilled shafts for a typical bridge is limited. This model, as illustrated in Fig. 16, is based on representing the soil by a series of nonlinear springs. It provides a complete representation of the soil–structure interaction. Furthermore, nonlinear behavior as plastic hinging of the shaft cross-section can be included as well as soil yielding. This approach is usually required for bridges located in highly active seismic regions. Two analytical methods are available to establish the nonlinear springs. These are the p - y method and the strain wedge method. The p - y model, as described in section “[Pile](#)

[Foundation Stiffness](#),” simply describes the force displacement relationship of a soil spring, in which p is the soil reaction per unit length at a certain location along the embedment length of the pile into soil and y is the corresponding deflection of the pile. A major shortage of this method is that the p - y curves are semiempirical relationships and were developed based on a limited number of full-scale lateral load tests on piles of diameters ranging from 12 to 24 in.. Hence, they might underestimate the soil stiffness for larger diameter drilled shafts. Also, the p - y method uses a P -multiplier to account for group effects. Selection of values of this parameter is still controversial as treated by different codes and specifications. The strain wedge method (Ashour and Norris 1998), on the other hand, fills all these gaps. The nonlinear springs, obtained using this method, are based on modeling the three-dimensional interaction between the surrounding soil and the shaft. The method considers the alternative effects of the pile properties (stiffness and cross-section) and soil properties in developing the p - y curve. Furthermore, there is no need to use P -multipliers to the strain wedge method because this method accounts for the group effects through an assessment of the overlap of the passive wedges that develop due to

Bridge Foundations,
Fig. 16 Methods of
representing shaft
foundation stiffness

pushing the shaft in the lateral direction. For a group, the strain wedges for different shafts will interfere together, depending on the spacing, diameter, and location of the shaft within the group leading to strength reduction and softening.

The nonlinear spring modeling technique can include the Masing hysteretic behavior of the soil, which when implemented includes automatically in the model the energy dissipation associated with material damping. The radiation damping component can be included by attaching additional viscous dashpots. Recent studies (Wang et al. 1998) showed that placing the viscous dashpots (representing radiation damping in the far field) in series with the hysteretic component of the soil-structure element (representing the nonlinear soil-pile response in the near field) is technically preferable to a parallel arrangement of the viscous and hysteretic damping components.

Equivalent Cantilever Model

The equivalent cantilever model is the simplest approach to represent the effects of the surrounding soil, wherein the sectional properties of the cantilever are the same as that of the shaft, but its length (depth to fixity) is adjusted to provide the same maximum bending moment as in the actual

soil-pile system. The effective length of the shaft shall be equal to the laterally unsupported length L_C plus an embedded depth to fixity L_F . The depth to fixity below the ground in ft. may be taken as (AASHTO-LRFD 2012):

For clays:

$$1.4 \left[\frac{E_p I_w}{E_s} \right]^{0.25} \quad (10)$$

and for sands:

$$1.8 \left[\frac{E_p I_w}{n_h} \right]^{0.20} \quad (11)$$

Where E_p is the modulus of elasticity of the shaft material; I_w is the weak axis moment of inertia for the shaft; E_s is the soil modulus for clays; S_u is the undrained shear strength of clay; and n_h is the rate of increase of soil modulus with depth for sand.

Coupled Foundation Stiffness Matrix

This approach is usually employed in regions of low to moderate seismicity. As illustrated in Fig. 16, a 6×6 can be determined for a single shaft at the ground line. As indicated in section “[Coupled Pile Foundation Stiffness Matrix](#),”

linearization of p-y curves is required for the development of a 6×6 coupled stiffness matrix.

Seismic Design of Drilled Shafts

The following design requirements shall apply (ATC-32 1996) to bridges on drilled shaft foundations:

- (I) Seismic lateral foundation design forces shall be based on either plastic hinging of the bridge column or pier; linear dynamic analysis; or more advanced nonlinear dynamic response analysis.
- (II) Foundation stiffness must be accounted for in the dynamic response analysis of the overall bridge.
- (III) The capacity of shaft foundations and their individual components shall be based on the safety evaluation earthquake.
- (IV) Earth pressures generated by lateral ground displacements due to liquefaction shall be accounted for at poor soil sites.
- (V) Strong connection details shall be evaluated at poor soil sites.

Large Gravity Caissons

Large caissons are very large concrete boxes that are excavated or sunk to a predetermined depth. They are usually used for the construction of bridge piers or other heavy waterfront structures,

and they often become advantageous where water depths exceed 30–36 ft. Caissons are divided into three major types: (1) open caissons, (2) box caissons (or closed caissons), and (3) pneumatic caissons. A common feature of large caissons produced by the three methods is that they are massive structures that respond to seismic loads in a primarily rocking mode about the base plus some translations.

Seismic Evaluation of Large Caissons

The behavior of caissons under lateral seismic loads is essentially nonlinear. Geometric nonlinearity dominates this behavior due to rocking of the caisson and gapping at the soil-caisson interface. The weight of caissons constitutes the major portion of the entire structure due to its large volume. Hence, the fundamental natural period of vibration of the large caisson is short and very different from the long period response of the bridge. This difference in the two modes of vibrations enables uncoupled seismic analyses of the two structures. However, when evaluating the bridge structural response, the caisson as an element must be included in the total bridge model. Two approaches are usually used for representing large caissons for seismic design.

The uncoupled spring approach represents the caisson as a lumped mass and establishes the interaction between the caisson and soil by the impedance approach. Figure 17a displays a

Bridge Foundations, Fig. 17 Modeling techniques of caisson foundations: (a) Uncoupled spring approach; and (b) Winkler approach

Bridge Foundations,
Fig. 18 Continuum
 models of caissons

schematic of the caisson model using this approach, wherein a rigid link is established between the node located at the center of mass of the caisson where its mass is lumped and another node at the bottom where a set of springs is attached. This method has been presented in section “[Spread Footing Stiffness](#).” This method overlooks the propensity of gapping at the base and at the embedded sides of the caisson during the seismic event and may lead to irrelevant results in the large displacement range of loading. Hence, it is only recommended for regions of low seismicity.

The nonlinear spring Winkler approach (Fig. 17b), as mentioned earlier, treats the soil supporting the foundation as a series of springs. It represents linear and nonlinear soil properties and hence favorable for life safety performance based design. It also accounts for the separation and gapping between the caisson walls and the surrounding soils. The properties of these nonlinear springs are established through static pushover analyses of three dimensional finite element continuum models as. Figure 18 depicts an example of such continuum model, where both the caisson and surrounding soil are modeled by three dimensional brick elements. The detailed 3-D finite element shall include constitutive relationships for the nonlinear behavior of the soil and special interface elements that can capture gapping

between the soil and the caisson at the base and side walls. Nonlinear static pushover analyses shall be carried out to establish the soil–structure interaction behaviors for implementation in the global model. Pushover analyses of the local model shall be performed by applying a point load at the center of gravity of the rigid caisson for each mode of soil resistance. The soil response results from the different pushover analyses of the local model in each direction shall be extracted and distributed to the soil spring elements at various nodal points in accordance with the discretization scheme of the global model. The behavior of the caissons under seismic loads shall be assessed through nonlinear time history analysis of the global model. The performance of the caissons is evaluated by comparing the maximum drifts from the results of the time history analysis to the permissible levels according to the performance based design criteria of the project.

Introduction

For a structural engineer, selection of the lateral load-resisting system for a building is a critical decision. While it is easy to understand the requirement to select beams and columns to support the gravity loads (i.e., self-weight of the building itself and the live loads related to building occupancy), a lateral system is required for any building to resist horizontal loading. Lateral loads routinely considered in design are wind and earthquake, although blast, flood, and tsunami are also possible. The lateral system can be especially critical when the building is to be constructed in a region where significant seismic activity is expected. In the case of a steel building, a wide variety of lateral resisting systems are available. These tested and approved lateral systems have the capability to maintain structural integrity in the face of significant lateral loads and inelastic behavior. One of the key elements to steel structures resisting seismic loads is a properly designed energy-dissipating fuse element. This critical element yields and subsequently dissipates energy during an earthquake without causing instability or collapse of the structure. In moment-resisting frames, the beams and columns resist both gravity and lateral loads although typically only the perimeter frames resist lateral forces. In this case, the beam elements are the fuse where inelastic behavior is expected. The challenge with these systems is that repairing or replacing beams after an earthquake is extremely difficult and costly. The other common lateral resisting system for steel buildings is a braced frame. The three most common braced frame systems are concentrically braced frames (CBF), eccentrically braced frames (EBF), and buckling-restrained braced frames (BRBF). Representative schematics for all three steel brace systems are shown in Fig. 1. Buckling-restrained braces (BRB) are a somewhat recently developed structural device that has a balanced force-deformation behavior (i.e., nearly equal strength in tension and compression) and are one of the few manufactured, rather than fabricated, products in common use in the structural steel construction industry. This entry will briefly

explore the three common types of braced frames and then discuss in greater depth the mechanics, performance, and design of BRBs and the BRBF system.

Steel Braced Frame Lateral Resisting Systems

The basic premise of braced frame systems is that diagonal braces are placed in certain bays creating a vertical truss system to resist lateral loads. This results in primarily axial forces and axial deformations to control response of the lateral force-resisting system. The most common type of braced frame is the concentrically braced frame (CBF) (Fig. 1a). For CBFs, the centerline of the braces, beams, and columns is concentric at beam-column-brace joints and beam-brace intersections so that axial forces are induced in the braces, beams, and columns and significant moments are not developed in the members. The braces are the fuse elements, and the stiffness and strength of the system are controlled by the geometric and material properties of the braces. There are several drawbacks to this system, the first being the asymmetry of the system due to the braces yielding in tension and buckling in compression. This unbalance results in a significant difference in brace forces as well as degradation in both strength and stiffness during an earthquake. In addition, the potential exists for brace fracture due to multiple cycles of compression buckling and tension yielding. The benefit of this system is that typically the system is stiff resulting in small interstory drifts. CBFs have been extensively studied and tested experimentally such that if proper detailing methods are followed, the structure will be safe and the braces can be replaced following a significant earthquake.

A second type of braced frame is the eccentrically braced frame (EBF) (Fig. 1c). For these systems, the braces are intentionally eccentric relative to the element joints resulting in a combination of axial, shear, and moment in certain structural elements. The fuse element in this case is typically a link beam. The case shown in

Buckling-Restrained Braces and Their Implementation in Structural Design of Steel Buildings, Fig. 1 Types of steel braced frames

Fig. 1c shows a link in the middle of the beam span although it is also commonly adjacent to the column. The diagonal braces used in EBFs are designed to remain elastic for the maximum forces and moments that can develop in the link beam. An EBF system is more flexible than a CBF and has a symmetric response as the yielding under shear and flexure is symmetric. The primary drawback for EBFs is that replacing the link beam is more difficult and costly than replacing a diagonal brace. There has been recent work in developing and testing replaceable link beams to overcome this problem (Mansour et al. 2011).

The third type of braced frame system is the buckling-restrained braced frame, which is a type of concentrically braced system. The BRB is the primary structural element in the BRBF providing the necessary ductile energy dissipation. The difference between a typical fabricated steel

brace and the BRB is the symmetry of the response. A BRB is specially designed to prevent buckling during the compression cycle. This results in highly ductile behavior in both tension and compression and prevents the force unbalance present in other brace configurations due to the significantly lower buckling strength as compared to the tension yield (see Fig. 1b). Brace fracture is not a problem due to the fact that the large stresses in the core are primarily axial. There is no strength or stiffness degradation for BRBs that are detailed correctly. The stiffness of a BRBF is less than a CBF as the BRB strength is directly related to the tension strength, whereas in a CBF the area generally must be increased to get the required capacity in compression. Buckling-restrained braces are unique in that they are a manufactured device rather than a fabricated steel section. Since their development and introduction into the industry, BRBs have taken a

Buckling-Restrained Braces and Their Implementation in Structural Design of Steel Buildings, Fig. 2 Isometric cutaway of buckling-restrained brace

large market share in braced steel frame systems due to their cost competitiveness and their reliable, resilient performance in seismic events.

Buckling-Restrained Brace Description

Because braced frames have very beneficial characteristics, significant work was undertaken to determine ways to overcome the negative aspects of brace buckling. The early beginnings of a brace restrained against buckling were in the 1970s in Japan where steel plates were encased in a precast concrete wall (Wakabayashi et al. 1973). Since then, significant improvements and modifications have been made to the original configuration that has enabled the reliable and ductile BRB commonly used today (Black et al. 2004; Fahnestock et al. 2006; Xie 2005). The key to the mechanism is the axial load going through the steel core while sufficient buckling resistance (flexural rigidity) is provided in another component. This has been accomplished in several ways although the most common is shown in Fig. 2. The basic premise of the BRB is that the core steel element has a cross section designed to yield in tension and compression. In order for this to occur, sufficient flexural rigidity must be provided so the overall buckling load of the composite device is greater than the ultimate strength of the steel core. This is accomplished through the use of a steel tube which is most commonly square or circular. The core steel

runs through the center of the tube which is then filled with a mortar paste to fill the space allowing the steel tube to provide the required flexural resistance to brace the core. It is not desirable for any axial load to go through the mortar or the steel outer tube. This is accomplished by providing a bond breaker between the mortar and the steel core. Several different options have been used for this including a lubricant or a material wrapped around the steel core prior to filling the outer tube. In addition to the BRB shown in Fig. 2, several other systems have been developed by researchers to create a BRB system for lower cost, to simplify manufacturing, or to replace damaged cores more simply after an event. Several of the BRB systems developed through these research efforts are shown in Fig. 3, although this is a sample of the different variations that have been investigated. Figure 4 shows a photograph of a building retrofitted with BRBs.

The geometry and yield strength of the core section play an important role in the performance of BRBs. From a material specification, it is desirable to have a known value or at least a small range where yielding will occur. An A36 material with controlled yield is commonly used for this purpose. The yielding core section can be fabricated to any area specified by the structural engineer. The area of the yielding core is the prime cross-sectional characteristic used to determine strength. There are two primary shapes for the core region, flat plate or cruciform.

Buckling-Restrained Braces and Their Implementation in Structural Design of Steel Buildings,

Fig. 4 Photograph of building retrofitted with BRBs (Courtesy of Core Brace, LLC)

In addition, some BRBs use multiple cores within the restraining tube to achieve the desired core area. The length of the yielding core is an important part in determination of the stiffness of the brace. Figure 5 shows the breakdown of a typical core with the flat plate yielding core, transition region, and connection region. The flexural stiffness of the transition region and connection region is important as the flexural rigidity of these regions must be sufficient to sustain the

core axial strength. The equation for the equivalent elastic stiffness of the brace is shown in Fig. 4 and is based on a combination of springs in series representing the axial stiffness of each segment. The overall stiffness of the brace is important for accurate analysis of the frame with BRBs and can be modified if the brace stiffness is too low. This modification is typically done by shortening the yielding core length (i.e., increasing the transition length) which is the most flexible segment.

 buckling-restrained brace
 and concentric brace

However, it is important to recognize that a shorter yielding length results in higher inelastic strains in the core which will result in higher forces in the braces, an important design criterion.

The overall representative hysteretic behavior of a BRB and a concentric brace is shown in Fig. 6. The BRB has full hysteresis loops in both tension and compression including strain hardening. The capacity for significant deformation ductility in both directions is apparent where deformation ductility is defined as the total

deformation divided by the yield deformation. There is a small increase in strength on the compression side, typically about 10 % larger than the brace tension strength. This is due to friction between the core and the mortar. Even with a bond breaker, the core will dilate under compression resulting in greater frictional force and some axial load transfer. By contrast, a concentric brace performs well in tension but experiences buckling in compression which typically results in formation of a flexural plastic hinge near the

center of the brace. Once the brace has buckled one time, it quickly loses strength in compression upon subsequent cycles. The formation of the hinge can result in brace fracture in tension due to the damage occurring during compression buckling. The lower compression capacity and potential brace fracture significantly limit the energy dissipation and deformation ductility capacity of CBFs when compared to BRBs.

As was stated previously, BRBs are a manufactured product. In the United States there are three primary brace producers, Core Brace (<http://www.corebrace.com/>), Star Seismic (<http://www.starseismic.net/>), and Unbonded Brace (<http://www.unbondedbrace.com/>). Each of these companies has tested their braces to meet the requirements put forth in the applicable building codes and reference documents. In addition to the braces, they provide design and engineering guidance associated with their products. While the basic premise of the BRB is the same for each manufacturer, many specific details of the various brace manufacturers differ as they compete based on price and performance in the marketplace.

BRBs, as manufactured products, have a high degree of quality control requirement placed on them in the American Institute of Steel Construction (AISC) *Seismic Provisions for Structural Steel Buildings* Section K3 (AISC 2010), which is a reference standard in the United States (USA) governing the design of steel buildings for seismic loads. The requirements include testing which includes both axial demands on the brace and the consideration of rotations at the connections due to frame deformations. The primary requirements of the testing are to show (1) the required ductility, both for a single cycle and cumulatively; (2) repeatable stable hysteresis with positive post-yield slope; and (3) avoidance of core rupture, brace instability, and connection failure. The required testing for a wide variety of brace sizes has been completed by the three primary producers. The specification however allows for these tests to be run on a project-specific basis if a new or unique brace configuration is specified.

Buckling-Restrained Brace Design

Buckling-restrained braces were first used in the USA in 1999, over a decade after the first usage in Japan in 1987 (UBB 2014). Part of the motivation for this new system was due to the failure of steel moment frames that occurred in the 1994 Northridge, California, and the 1995 Kobe, Japan, earthquakes. As with other new developments in structural engineering practice, it was implemented in building practice in the USA prior to inclusion in building codes or reference standards. The first inclusion of BRB design provisions was in the *NEHRP Recommended Provisions for Seismic Regulations for New Buildings and Other Structures* (FEMA 2003), FEMA 450. The information included in FEMA 450 was developed by a joint committee including AISC and the Structural Engineers Association of California (SEAOC). FEMA 450 is not a building code or reference standard, but inclusion is typically the first step in the process. The buckling-restrained braced frame was included in the 2005 version of ASCE/SEI 7, *Minimum Standard for Design Loads for Buildings and Other Structures* (2005), as an acceptable seismic force-resisting system. In ASCE/SEI 7-05, a BRBF had the following seismic performance factors (SPF): $R = 7$, $\Omega_o = 2$, $C_d = 5.5$. A dual system with BRBs and moment-resisting connections at the beam-column joints without a bracing connection had slightly different SPFs: $R = 8$, $\Omega_o = 2.5$, $C_d = 5$. One change of note that appeared in ASCE 7-10 was that the SPFs for BRBs with and without moment frames were made the same as the dual system based on research that had taken place in the interim. In addition to ASCE 7, BRB provisions were included in AISC Standard 341-05, *Seismic Provisions for Structural Steel Buildings* (2005). This document deals with more detailed requirements for design of not only the BRBs but also the other elements of the lateral force-resisting system. This document also lists the required testing protocol for BRBs. The subsequent versions of the ASCE/SEI 7 and AISC 341 standards continued to include provisions for BRBs with

modifications based on continuing research. An early and still applicable reference for the design of BRBs is by Lopez and Sabelli (2004) which has detailed examples of design provisions. A more recent textbook (Bruneau et al. 2011) also has a chapter on BRBFs.

From the design perspective, sizing of BRBs is a very straightforward process. The size of the core is based on the maximum axial demand according to the limit state of yielding based on the load combinations from the applicable building code. Equation 1 shows the basic premise where P_{ysc} is the nominal axial yield strength, A_{sc} is the area of the steel core, and F_{ysc} is either the minimum specified yield stress or the actual yield stress from a coupon test. If the manufacturer provides coupon tests from the steel used to fabricate the core, this value can be used in design. Otherwise, a range of values should be used to determine the upper and lower limits that could occur.

$$P_{ysc} = F_{ysc}A_{sc} \quad (1)$$

Once determined, the nominal yield strength value is then modified by a resistance factor of 0.9 for LRFD design to determine the design axial strength. One of the benefits of BRBs is that any cross-sectional area can be provided so each floor can have a BRB sized to the demand. Typically the area will be rounded to some degree based on the manufacturer's practice, but this is not generally a significant change. In addition to nominal yield, the adjusted brace strength must also be established as part of the design. The adjusted brace strength has two components, the tension ($\omega R_y P_{ysc}$) and compression adjusted brace strength ($\beta \omega R_y P_{ysc}$), where ω is the strain hardening adjustment factor, β is the compression strength adjustment factor, and R_y is the ratio of expected to specified minimum yield stress. R_y can be set to 1 if coupon tests are used to determine the yield strength. The values for β and ω are taken from coupon tests that are carried out to the strain equivalent to that occurring in the brace at the expected deformation. The expected deformation is defined as the larger of 2 % story drift or two times the design story drift. Figure 7 shows a

plot of how these values would be determined. This is one of several items that will require input from a brace manufacturer. The adjusted brace strength is used to ensure that the beams, columns, and connections in the frame have the required strength to remain elastic through the expected strength of the BRB. The design of brace connections must be designed to 1.1 times the adjusted brace strength in compression.

The other component of design that is important is accurate modeling of brace stiffness. As discussed previously, the stiffness of the brace represents a combination of the stiffness of the different segments. This versatility provides additional mechanisms to control response by modifying the stiffness of the brace. For example, if the brace is too flexible, the yield length could be shortened. However, this will have an effect on other components as the inelastic strains in the brace for the same deformation will increase which will also increase the adjusted brace strengths. Brace manufacturers will provide assistance to create the appropriate balance of stiffness and required strength.

One of the final design considerations is that of the connection of the BRB to the framing. There are three typical options for connecting BRBs to gusset plates although the specific details of the connections vary based on the different manufacturer's brace geometry. The three options are bolted, welded, and pinned connections. Example details are shown in Fig. 8 although many variations can be found and have been used. As opposed to CBFs where the gusset plate is designed to allow for the out-of-plane rotation due to brace buckling, BRBs can sustain significant moments. These large moments are developed based on the large deformations in the frame inducing rotations in the beam and columns. The pin allows for these rotations to occur in the connection rather than the structural element. This allowance for rotation can also be developed using welded and bolted gusset connections by providing a beam stub off the column with a hinge connection to the remainder of the beam as shown in Fig. 8c. It is also of critical importance to ensure that the connection (gusset plate and end section of BRB) has sufficient

Buckling-Restrained Braces and Their Implementation in Structural Design of Steel Buildings,

Fig. 7 Determination of adjusted brace strength from test data

Buckling-Restrained Braces and Their Implementation in Structural Design of Steel Buildings,

Fig. 8 Typical gusset plate connection details

out-of-plane flexural resistance to resist buckling up to the full strength of the core section. Typical gussets for BRBFs are markedly smaller than those used in CBFs.

In addition to typical frame structures, BRBs can be used anywhere a ductile fuse element is required. Examples include bridges as ductile connections between the superstructure and the substructure, stadiums as part of the lateral resisting systems, and dam intake towers to prevent lateral motion while limiting the forces imparted to the dam. They have also been used more recently in the San Francisco Airport Air Traffic Control Tower which is a self-centering system where the BRBs provide hysteretic energy dissipation (Muthukumar and Sabelli 2013).

It is interesting to note that the design for BRBs in Japan is different from the USA. In Japan, braced frames are designed to higher force levels than moment frames (i.e., the equivalent of the R value penalizes braced frames) due to the potential for buckling. Because of this fact, most low-rise construction in Japan is designed with moment frames. However, for taller buildings, BRBs are used significantly due to the increased stiffness. In order to use BRBs for their stiffness and energy dissipation without the force penalty, they are used as hysteretic energy-dissipating devices as part of a dual system with moment-resisting frames (Xie 2005). The first reported use of a BRB in Europe was in 2006 at the University of Ancona in Italy. Use of BRBs in Europe is much less than in Japan and the USA (Della Corte et al. 2011).

Buckling-Restrained Brace Innovations

Buckling-restrained braces are one of the more impactful developments in earthquake engineering. They are considered today a standard option for both new designs and retrofits of existing buildings in significant seismic hazards. However, as with any innovation, additional improvements are constantly explored to further improve

on the existing concept. One of the biggest weaknesses of BRBs that has been identified in analytical and experimental research is residual displacements following significant earthquakes. The modifications and/or additions to BRBs have primarily aimed to reduce residual deformations in BRBFs. This movement is also centered on a larger goal of providing a higher performance standard than life safety in buildings for major earthquakes. Since BRBs are an effective lateral system, additions and modifications to a high-performance seismic system represent an ideal way to move toward damage reduction in addition to life safety.

The first of these innovations is called the hybrid passive control device (HPCD). The HPCD consists of a BRB in series with a viscoelastic damping device. For small deformations, only the viscoelastic damper is active. After a specified displacement, the viscoelastic device locks out and the BRB becomes active. The device was tested in the laboratory and implemented in analytical models of a nine-story structure. Experimental testing showed the concept worked as designed. The building response to a suite of earthquakes was improved, and residual displacements were reduced when compared to a BRB frame (Marshall and Charney 2010a, b).

One of the ways that has been explored to improve building response and reduce damage is through the use of self-centering systems. The idea of these systems is to provide an element that remains elastic while a fuse element yields and dissipates energy. Analytical and experimental research was completed on a self-centering buckling-restrained brace (SC-BRB) using nickel-titanium-based shape memory alloys. The shape memory alloy's unique properties provide the capacity to self-center in addition to providing additional energy dissipation. The SC-BRB consists of typical BRB with two additional outer concentric tubes and free-floating end plates so the shape memory alloy rods were always loaded in tension. The experimental testing showed significant capacity for energy

dissipation, deformation ductility, and self-centering which would result in a lateral system with the ability to reduce structural response and limit residual damage in the event of a large earthquake (Miller et al. 2012).

An additional innovation associated with BRBs is the use of a multi-core BRB with different steel grades, called a hybrid BRB (HBRB). The idea of using a low yield stress steel core (100 MPa/14.5 ksi) in combination with a typical or higher yield stress steel presents a unique option. Since the modulus of elasticity is the same for the two steels, the low yield stress steel will yield earlier and begin to dissipate energy while the structure still has significant stiffness. The system can be optimized based on the ratio between the area of low yield point steel and the other steel in the BRB. The idea here is to dissipate significant energy before the structure reaches a state where the stiffness has decreased significantly. This concept has been shown to reduce residual displacement and decrease the number of simulated collapses when compared to typical BRBFs (Atlayan and Charney 2012).

Summary

Buckling-restrained braced frames are a resilient lateral system for structural steel buildings. The ability to control both the stiffness and strength, nearly independently of each other, and the large, full hysteresis loops makes a BRBF an effective seismic system that can be designed for many different hazards. BRBs are versatile and can be used in many different types of structures including both new construction and seismic retrofits. This has been demonstrated by both the increase in usage for construction projects and the continued worldwide experimental research, both completed and ongoing. As with any lateral resisting system, there are weaknesses which need to be resolved. Continued improvement through research and development will continue to improve performance of this ductile lateral resistance system.

"Build Back Better" Principles for Reconstruction

Sandeeka Mannakkara, Suzanne Wilkinson and Tinu Rose Francis
Department of Civil and Environmental Engineering, The University of Auckland, Auckland, New Zealand

Synonyms

BBB; Reconstruction; Recovery

Introduction

"Build Back Better" signifies an ideal reconstruction and recovery process that delivers resilient, sustainable, and efficient recovery solutions to disaster-affected communities. The motivation behind the Build Back Better concept is to make communities stronger and more resilient following a disaster event. Statistics from the United Nations Environment Programme in 2008 show an increase in the number of natural disasters over time attributing to growing populations,

urban growth in risk-prone areas due to scarcity of land, and global warming. Along with increasing frequency, recent disasters show an increase in magnitude and resulting destruction according to studies by the Red Cross. Both natural and technological/man-made disasters have seen nearly exponential rises in the number of disasters over time.

Despite the increasing number of disaster experiences, post-disaster activities remain inefficient and poorly managed and need to be improved according to Halvorson and Hamilton (2010). Traditionally, post-disaster reconstruction consisted of simply repairing the physical damage that has been induced by a disaster. However, Kennedy et al. (2008) pointed out that rebuilding the built environment and infrastructure exactly as they were prior to a disaster often re-creates the same vulnerabilities that existed earlier. If restored to pre-disaster standards, disaster-affected communities would face the same difficulties if exposed to another disaster event in the future. The reconstruction and recovery period following a disaster poses an opportunity to address and rectify vulnerability issues found in communities.

As a result of witnessing the ongoing impacts of disasters on communities, a concept started to emerge where post-disaster reconstruction was to be taken as an opportunity to not only reconstruct what was damaged and return the community to its pre-disaster state but to also seize the opportunity to improve its physical, social, environmental, and economic conditions to create a new state of normalcy that is more "resilient" (Boano 2009). This concept was termed "Build Back Better," suggesting that successful recovery of communities following disasters needs to amalgamate the rehabilitation and enhancement of the built environment along with the psychological, social, and economic climates in a holistic manner to improve overall community resilience. The phrase "Building Back Better" became popular during the large-scale reconstruction effort following the Indian Ocean Tsunami disaster in 2004 after which it became more officially embraced with the creation of sets of BBB Guidelines to steer recovery and

reconstruction activities toward achieving this goal (Clinton 2006).

This chapter reviews what BBB entails and presents the key elements required to improve post-disaster reconstruction and recovery practices to build back better. First, existing guidelines and reports providing recommendations for BBB are introduced. Key information from the guidelines and reports is used to then identify the key concepts which represent Building Back Better. Finally, each concept and its importance for building back better are reviewed.

The Need for Building Back Better

The South Asia Disaster Report (DNS and PA 2005) states that disasters are produced due to the weaknesses and vulnerabilities of communities, countries, and structures to withstand encountered hazards. Wisner et al. (2004) defines vulnerability as the lack of capacity to anticipate, cope with, resist, and recover from the impact of a hazard. The destruction and loss of human lives from the 2005 Kashmir Earthquake in Pakistan was primarily due to the collapse of inappropriately built structures constructed on earthquake-prone land using substandard building materials and designed with little earthquake resistance. Poorly planned and sometimes illegal developments and their resulting impacts on the environment worsened the damage from the Mumbai Floods in 2005. A similar situation was seen in Sri Lanka after the Indian Ocean Tsunami.

Restoration of the damaged physical, social, economic, and environmental impacts of disasters is a complicated and drawn-out process. Reconstruction and recovery projects often focus on quick restoration of affected communities which can replicate and worsen existing vulnerabilities faced by the community. The Tsunami Evaluation Commission Synthesis Report in 2007 provided examples where escalated pressures and the need for fast rebuilding and recovery processes following a disaster can further increase the vulnerability of a community. Examples include: nonadherence to design and construction policies for buildings and

infrastructure, insufficient focus given to certain aspects of the recovery process such as livelihood development programs and small business support programs, overruling of local government agencies, and neglecting vulnerable groups of people in the community.

Complete recovery requires attention to many different elements. BBB was defined by Khasalamwa (2009) as a way to utilize the reconstruction process to improve a community's physical, social, environmental, and economic conditions to create a more resilient community, where resilience is defined as "the capacity to recover or 'bounce back' after an event" (Twigg 2007). Therefore, what the concept of BBB proposes is a broad holistic approach to post-disaster reconstruction in order to address the wide range of prevalent issues including those mentioned above and ensure that affected communities are regenerated in a resilient manner for the future.

Existing Guidelines for Building Back Better

Clinton's (2006) "Key Propositions for Building Back Better" was the earliest known official document to be published which attempted to provide a comprehensive guideline for implementing BBB practices in post-disaster environments. The report was based on and aimed at the Indian Ocean Tsunami disaster. He introduced ten propositions for building back better.

Clinton's propositions were:

- Proposition 1: Governments, donors and aid agencies must recognize that families and communities drive their own recovery.
- Proposition 2: Recovery must promote fairness and equity.
- Proposition 3: Governments must enhance preparedness for future disasters.
- Proposition 4: Local Governments must be empowered to manage recovery efforts, and donors must devote greater resources to strengthening Government recovery institutions, especially at the local level.

- Proposition 5: Good recovery planning and effective coordination depend on good information.
- Proposition 6: The UN, World Bank, and other multilateral agencies must clarify their roles and relationships, especially in addressing the early stages of a recovery process.
- Proposition 7: The expanding role of NGOs and the Red Cross/Red Crescent Movement carries greater responsibilities for quality in recovery efforts.
- Proposition 8: From the start of recovery operations, Governments and aid agencies must create the conditions for entrepreneurs to flourish.
- Proposition 9: Beneficiaries deserve the kind of agency partnerships that move beyond rivalry and unhealthy competition.
- Proposition 10: Good recovery must leave communities safer by reducing risks and building resilience.
- Monday's "Holistic Recovery Framework" in 2002 which addresses enhancing the quality of life in the community, economic vitality, and the quality of the environment, risk reduction, and participatory decision-making in recovery activities
- Bam's Reconstruction Supreme Supervisory and Policymaking Association's "Bam's Reconstruction Charter" in 2010 which includes policies for reconstruction management; community participation, employing suitable construction technology and materials; preserving cultural and architectural heritage; and ensuring stability of construction
- Victorian Bushfire Reconstruction and Recovery Authority's "Recovery and Reconstruction Framework" in 2011 which focuses on the safety and well-being of the community, needs-based resource allocation, community engagement, equity, and tailored solutions
- Canterbury Earthquake Recovery Authority's "Recovery Strategy" in 2013 which entails leadership and integration to manage recovery activities using a participatory approach, regenerating the economy, restoring and enhancing the community, reconstruction of the built environment, and restoring natural and healthy ecosystems

Several other guidelines directly and indirectly proposing BBB-based recovery and reconstruction operations include:

- United Nations Disaster Relief Organization's "Principles for Settlement and Shelter" in 1982 which addresses stakeholder role allocation, needs-based provision of resources to the community, and risk reduction
- The Government of Sri Lanka's "Post-Tsunami Recovery and Reconstruction Strategy" and "Build Back Better Guiding Principles" in 2005 which include needs-based resource allocation and provision of locally appropriate solutions, community participation and consultation in recovery activities, equity, transparency between stakeholders, risk reduction and consideration of future sustainability, and livelihood support
- Federal Emergency Management Agency's "Rebuilding for a More Sustainable Future: An Operational Framework" in 2005 which mentions role allocation and coordination of stakeholders, community-centered recovery operations, and hazard-based sustainable risk reduction practices

Key Concepts

The concepts proposed to achieve BBB during reconstruction and recovery in the various guidelines in the previous section feature similarities. Aspects such as role allocation of stakeholders, community participation, and risk reduction appeared in most of the guidelines. The key concepts introduced in the guidelines for improving reconstruction and recovery efforts and building back better include: risk reduction, psychosocial recovery, economic recovery, effective implementation, and monitoring and evaluation. The next few subsections describe these key concepts in further detail.

Risk Reduction

Risk reduction identifies all actions taken toward reducing disaster risks in communities to improve the physical resilience in the built environment. Previous post-disaster experiences have emphasized the need to identify prevalent hazards and determine solutions to be undertaken to reduce risks imposed on people. The Red Cross's World Disaster Report in 2010 disclosed that the risks seen in cities are due to a number of reasons such as: growth in informal or illegal settlements, inadequate infrastructure, and building on sites at risk from hazards. The report also stated that many past disasters could have been anticipated and avoided with proper planning, design, and construction methods. The Victorian Bushfires Royal Commission Final Report in 2010 recommended the amendment of the Australian Building Code following the Victorian Bushfires ensuring greater safety standards. The Royal Commission suggested identifying bushfire-prone areas and adopting suitable building and planning controls.

The National Mitigation Strategy produced in Turkey following the Kocaeli and Duzce earthquakes of 1999 also stated the need for site-specific hazard identification before reconstruction as well as retrofitting and updating structural codes and the use of tax incentives to encourage mitigation work (Bakir 2004). The 2008 South Asia Disaster Report by the nongovernmental organizations Duryog Nivaran and Practical Action recommended producing hazard and vulnerability maps and enforcing building codes to avoid development-related disasters in the future. The two primary ways of risk reduction are through improving structural designs and through better land-use planning.

The importance of reviewing and changing building designs and codes to improve the structural integrity of buildings and infrastructure following a disaster is widely understood but is however less frequently attained successfully in practice due to a range of common issues. Poor regulative powers and the lack of strict enforcement can lead to building code changes being disregarded resulting in substandard structures

in the rebuild. When the Indian Ocean Tsunami struck, enforcement of building codes was mainly restricted to urban and suburban areas in Sri Lanka. The rural and coastal areas were the main victims of the disaster, where the lack of strict structural standards resulted in magnified damage (Pathiraja and Tombesi 2009). Extra costs incurred by adopting new technologies and materials to improve structural resilience also discourage compliance of new building codes worldwide (Batteate 2006).

The experiences of post-disaster reconstruction efforts worldwide have provided lessons which can be adopted when implementing structural changes to avoid the above mentioned issues and build back better. BBB theory suggests that hazard-based building regulations should be created using multi-hazard assessments in areas chosen for redevelopment and reconstruction. Consistent regulations and a strong legal framework are necessary to assist the adoption of building codes and regulations and ensure that structural changes improve the built environment (Clinton 2006). As structural improvements are expensive and unaffordable especially in post-disaster settings, long-term funding needs to be made available to cover extra costs for structural improvements and promote adoption. Quality of reconstruction can be maintained by arranging inspections during construction by local governmental authorities. Stakeholders involved in the rebuild such as builders, engineers, and architects should be trained on revised building codes and other specific requirements to avoid inconsistencies and produce good quality results in order to build back better.

A land-use planning strategy was used in the post-disaster recovery efforts following the Indian Ocean Tsunami and the Samoan Tsunami, resulting in the relocation of coastal communities further inland to prevent future impacts of coastal hazards (Kennedy et al. 2008). The mandatory resettlement operations in Sri Lanka and Samoa were problematic due to the lack of consideration given to the lifestyles of the local people which led to the loss of their sea-dependent livelihoods,

dissatisfaction with their new settlements, and illegal return of people to the original coastal lands (Kennedy et al. 2008). A recurring issue with relocation is the focus given to moving communities away from a certain hazard resulting in exposing communities to new unanticipated hazards. Well-intended land-use planning measures can also fail due to the lack of knowledge and awareness of local people who do not conform to new regulations and the lack of experience and knowledge of local governing authorities who do not enforce new regulations (Kennedy et al. 2008).

Therefore, it was recommended by Baradan (2006) that hazard assessments of current land sites and possible new land sites should be carried out, after which risk zone maps are to be created which divide the land into zones based on the level of risk. Appropriate land uses and new planning and building regulations based on the risk zone maps are to be created. The risk zone maps should be legislated and included in council development plans and approval permit procedures to ensure compliance. Examples, such as Taiwan's Mitigation Plans, the Philippines Municipal Maps, and the Christchurch City Plan in New Zealand following the Canterbury earthquakes, display successful application of BBB measures to create safer developments. If resettlement to lower-risk lands is opted for, Mannakkara and Wilkinson (2012b) recommend that a comprehensive resettlement strategy should be created with community consent which takes into account risk levels of new lands, community preferences, and livelihood and lifestyle opportunities offered in the new locations for resettlement to be a success.

DN and PA (2008) encourage educating communities about risks and the importance of risk reduction measures and engaging them in collective risk reduction efforts. The Participatory Flood Risk Communication Support System (PafriCS) developed in Japan to educate locals and other stakeholders including NGOs and local governments on flood risks and risk management strategies is an example of a participatory tool.

Psychosocial Recovery

Supporting psychosocial recovery of affected communities has been identified as essential for building back better (Davidson et al. 2007). Post-disaster recovery often focuses on providing fast solutions in an attempt to reestablish a sense of normality in affected communities as soon as possible (Khasalamwa 2009). The focus on speed results in overlooking the real needs of communities. The community is often not consulted to provide their input on reconstruction and recovery (Boano 2009). The lack of community consultation and participation leads to the provision of recovery solutions that are not suitable. For example, some of the new houses constructed in Sri Lanka by humanitarian agencies during the Indian Ocean Tsunami rebuild featured bathrooms made with half-heighted walls and shared bathrooms for males and females which were culturally unacceptable (Ruwanpura 2009). Locals were unhappy with the reconstruction of homes following the 1999 Marmara Earthquake in Turkey as their local life, culture, and aesthetics were not considered. Khasalamwa (2009) stated that insufficient attention to social, cultural, and ethnic facets of communities during recovery can exacerbate preexisting vulnerabilities. Separation during disasters and resettlement operations disrupt community cohesion and psychological recovery (Florian 2007).

Social issues arising in post-disaster environments are primarily related to social/cultural/religious/ethnic factors, and psychological factors. Reconstruction is a chaotic and stressful time for individuals who are also experiencing trauma. These communities require various forms of assistance as part of building back better. Personalized advice and one-on-one support provided to families in Columbia during the 1999 earthquake recovery were a success. Similar forms of personal assistance were provided during the Victorian Bushfire recovery in Australia as well. James Lee Witt Associates (2005) recommended arranging specialized assistance for vulnerable communities. Providing psychological support and counseling are essential during recovery. The establishment of information centers which

offer easy access to recovery-related information for the community is also recommended. Upholding a sense of community spirit and improving community cohesion through organizing group activities are recommended for social recovery. The Canterbury Earthquake Recovery in Christchurch proposed sports, recreation, arts, and cultural programs to engage the community and provide a sense of normality.

One of the first steps to be taken in post-disaster recovery efforts in order to build back better is to understand the local context of the affected community through needs assessments and surveys in order to provide appropriate assistance to satisfy the community (Khasalamwa 2009). The reconstruction and recovery policies must then be developed based on local requirements to support and preserve the local culture and heritage. Batteate (2006) stated that maintaining community involvement throughout recovery is integral for BBB success. The importance of decentralization to empower disaster-affected communities by enabling them to take responsibility of the recovery effort and become involved in decision-making has been stressed by literature. The establishment of community consultation groups is an effective way to communicate with the community. Community consultation groups consisting of community leaders from preexisting community groups and reputed members of the community to liaise between the wider community and governmental authorities have been successful in Sri Lanka and India. Existing community groups can also be called upon to assist with recovery activities.

Economic Recovery

Supporting economic recovery of the community and supporting livelihood regeneration and entrepreneurship are also an important part of recovery. Disasters cause damage to the economy of communities with the disruption of businesses and income-generating industries leading to issues such as high inflation rates and poverty. The adverse effects of disasters on the economy can also impede the overall recovery of a city. Hurricane Katrina displayed a disaster's long-term impacts on higher education and health

care in New Orleans, which were the foundations of the city's economy, eventually leading to a decline in population numbers as people moved away in search of better opportunities.

Post-disaster recovery efforts to date have shown support for economic recovery with strategies such as: "cash-for-work" programs, provision of business grants, "asset replacement" programs to provide industries with necessary resources, and training programs to up-skill locals and help them find work. In Aceh, Indonesia, tsunami-affected people were trained and employed in reconstruction to provide them with a source of income alongside the opportunity to become involved in their own recovery (Kennedy et al. 2008). In Japan following the 2011 earthquake and tsunami, the government decided to consolidate smaller fishing markets into large fishing centers to enable fishermen to support each other (Okuda et al. 2011). The Christchurch City Council's Central City Plan proposes fast-tracking of building consents for businesses to allow faster repair and construction work. Despite the implementation of such initiatives, post-disaster economic recovery is reportedly slow and below pre-disaster levels. The lack of success in economic recovery initiatives can be attributed to insufficient backing from policies and legislation for employment creation and lack of consideration given to the needs of affected communities.

Clinton (2006) said in his BBB propositions that "a sustainable recovery process depends on reviving and expanding private economic activity and employment and securing diverse livelihood opportunities for affected populations." Thus, the uniqueness of BBB comes from the integrated approach it proposes by giving economic recovery as much importance as reconstruction and aiming to provide solutions to suit local dynamics and preferences.

Monday (2002) stated that one of the first steps needed for effective economic recovery is to obtain accurate information about the local population through data collection and consultation with local governmental authorities, and a comprehensive economic recovery strategy must be created that is tailor-made to suit each

different community based on data obtained. Where applicable, attractive and flexible low-interest loan packages, business grants, and resources should be provided to support the livelihoods of the disaster-affected. Training programs should be held to support people in improving their existing livelihoods or acquire new skills. Mannakkara and Wilkinson (2012a) propose that business support and counseling services should be provided to assist with the economic recovery. Rebuilding of businesses must also be facilitated through special fast-tracked permit procedures. Incentives such as subsidized accommodation must be provided to attract builders from other areas to participate in rebuilding.

Effective Implementation

A successful recovery effort requires effective and efficient recovery solutions as part of building back better. Two ways in which the efficiency and effectiveness of post-disaster recovery can be improved are through better management of stakeholders and through the use of appropriate post-disaster legislation and regulation.

One of the most common issues with post-disaster environments is the difficulty in coordinating between stakeholders to produce a unified outcome. Initially, there is often no organization in charge of the overall recovery effort. The lack of guidance leads different stakeholders to participate disjointedly promoting personal agendas which conflict with the interests of the local community (Batteate 2006). For example, nongovernmental organizations (NGOs) who operated in Sri Lanka following the Indian Ocean Tsunami constructed homes which were unsuitable for locals and were largely abandoned. The pressure for fast results during recovery also prevents well-intentioned stakeholders from considering community needs. Ambiguity about the roles of different stakeholders is another issue. The Victorian Bushfires Royal Commission report, 2010, stated that the roles of personnel involved in the recovery effort were unclear which led to the duplication of some activities. Many stakeholders involved in recovery have no previous experience in post-disaster

environments leading to ad hoc responses (Kennedy 2009). Often post-disaster interventions are governed by the national government without sufficient consultation or power given to local councils (Clinton 2006). Local-level organizations with useful local knowledge lack the capacity to operate to their full extent when impacted by disasters and are therefore excluded from recovery efforts. The lack of proper role allocation, coordination, and involvement of local-level stakeholders is a common issue found in post-disaster reconstruction environments.

A step taken to improve the management of large numbers of stakeholders in major disasters in order to build back better is the creation of a separate body to act as a recovery authority. Examples of recovery authorities created to manage reconstruction include: the Bureau of Rehabilitation and Reconstruction (BRR) in Indonesia following the Indian Ocean Tsunami, Bam's Reconstruction Supreme Supervisory and Policymaking Association (BRSSPA) in Iran following the 2003 Bam Earthquake, the Victorian Bushfire Reconstruction and Recovery Authority (VBRRA) in Australia following the 2009 Victorian Bushfires, and the Canterbury Earthquake Recovery Authority (CERA) following the 2010 and 2011 Canterbury earthquakes in New Zealand. The recovery agencies contributed to the success of recovery to differing extents. Clinton (2006) said that stakeholders must operate with a common set of standards, approaches, and goals in order for recovery to be a success. Twigg (2007) proposes that the recovery authority should be responsible for establishing clear roles and responsibilities for the different stakeholders to divide recovery tasks based on resources and skills and avoid duplication.

Functional partnerships and linkages established between organizations can enhance reconstruction projects. Post-disaster recovery is a unique environment which requires deviation from normal procedures. Information sharing between organizations is one such deviation. The Federal Emergency Management Agency in the United States advocates the sharing of information, contacts, resources, and technical

knowledge between organizations to help recovery activities (FEMA 2000). Knowledge from past disasters should be retained and transferred to the government and other relevant organizations who will be involved in future post-disaster efforts. Twigg (2007) recommends that local government should be included as a key stakeholder in the recovery effort and also given the responsibility to manage local-level activities.

Another obstacle preventing successful BBB-centered recovery is the absence of proper controls to enforce BBB principles. Having BBB knowledge and producing recovery plans in-line with these principles are futile without proper legislation and regulations in place to ensure they are implemented. A common challenge in post-disaster environments is the sudden increased work load, especially in the building industry, along with a drop in the workforce across local organizations which slow down and impede recovery activities. Post-disaster reconstruction requires time-consuming activities such as hazard analysis, land selection, infrastructure development, and rebuilding to be done in a relatively short period of time. It is important to facilitate recovery-related activities by simplifying, fast-tracking, and exempting certain rules and regulations using special legislation.

Post-disaster legislation can be used to ensure compliance with BBB-based activities as well as to facilitate normal operations to improve the efficiency of recovery efforts. The lack of enforcement of hazard-related laws and adequate risk-based building controls contributed to the large-scale devastation caused by the 2004 Indian Ocean Tsunami (DNS and PA 2005). The same was seen in countries like Pakistan, Turkey, Samoa, and Haiti. Enforcing updated risk-based building design standards through the use of compulsory building codes and maintaining construction standards through careful inspections is an important regulatory requirement in reconstruction (James Lee Witt Associates 2005). Lack of awareness and understanding of new legislation can also lead to noncompliance. In the post-tsunami recovery effort in Sri Lanka, external nongovernmental organizations (NGOs) who took part did not comply with local standards

due to unawareness (Boano 2009). The National Post-Tsunami Lessons Learned and Best Practices Workshop held in Sri Lanka in 2005 highlighted the importance of training stakeholders (especially external NGOs) about existing and newly introduced legislation and regulations. The community's support can also be obtained by educating them about legislation and regulations that must be adhered to in reconstruction and recovery.

Post-disaster legislation can also be used to simplify and assist recovery activities to speed up the recovery process. Legislation that is customarily used to impose security and safety controls (such as building consents) can become an obstacle in high-pressure post-disaster environments. Time-consuming procedures, insufficient resources to process permits, and the lack of fast-tracked methods delay reconstruction. Delays in permits were a major reason for the holdup in housing repair and rebuilding following the 2005 Bay of Plenty storm in New Zealand (Middleton 2008). Fast-tracked consenting procedures, collaboration with other local councils, and open access to information between stakeholders can help speed up recovery.

Legislation can be used to remove unnecessary red tape to facilitate recovery activities. Meese III et al. (2005) reported a good example in the recovery following the 1994 Northridge Earthquake, USA, where legislative suspensions and emergency powers greatly reduced highway reconstruction time. The construction work provided employment and opening up the highways soon after the disaster helped boost the economy.

Monitoring and Evaluation

The effectiveness and efficiency of post-disaster reconstruction and recovery activities is crucial to the success of a community's restoration following the impact of a disaster event. Having the knowledge of Build Back Better concepts in designing recovery programs is insufficient without systems in place to overlook and monitor implementation. The creation of a recovery strategy to assist in conducting post-disaster reconstruction and recovery activities is a common response following disaster events. Despite

having recovery strategies and revisions in legislation and regulation to improve recovery activities, the findings by Tas (2010) indicated that compliance was not monitored in the respective recovery efforts in Sri Lanka and Turkey, leading to poorly executed recovery projects. The lack of properly trained professionals who were competent in post-disaster environments and disaster management activities poorly affects the outcome of recovery efforts. The shortage of effective information and knowledge sharing and dissemination are also reasons for unsatisfactory disaster management practices. Findings from the Business Civic Leadership Center in 2012 on "What a Successful Recovery Looks Like" raised concerns that long-term recovery beyond reconstruction often does not take place due to the lack of mechanisms and expertise which prevents affected communities from satisfactorily "building back better" in the long run.

Recommendations to improve post-disaster recovery efforts through monitoring and evaluation have been provided in many sources of literature. The role of monitoring and evaluation is twofold: (1) to monitor and ensure compliance of recovery activities in accordance with the recovery strategy in place and relevant guidelines and regulations (Clinton 2006) and (2) to obtain lessons for the future and improve future disaster management and post-disaster reconstruction and recovery efforts (Monday 2002).

The 2003 Bam earthquake reconstruction provided a good example where rebuilding was monitored by providing construction supervision which assisted in assuring the quality of the rebuild. Clinton (2006) stated that the Tsunami Recovery Impact Assessment and Monitoring System (TRIAMS) was put in place during the Indian Ocean Tsunami recovery for the most affected countries. The recovery strategy in Christchurch, New Zealand, has also been equipped with monitoring mechanisms. Clinton (2006) suggested that long-term recovery should be monitored through continued data collection to ensure that recovery efforts do not leave communities with residual issues.

Monday (2002) pointed out that monitoring can be used to identify problems with post-

disaster interventions and establish lessons learnt. Lessons learnt should be incorporated into revising policy and procedures for future disaster management practices. Bakir (2004) recommends that public education campaigns should be run on lessons learnt, including the community in participatory disaster management. Public seminars have been held and advice notes have been distributed in Australia during the Victorian Bushfires recovery to keep the community informed about revised guidelines and standards. Workshops have been held in the Philippines, Japan, and California involving the community in vulnerability identification which have been successful (Batteate 2006).

Summary

"Build Back Better" is an important concept for post-disaster reconstruction and recovery, signifying the need to use reconstruction as an opportunity to not only recover from the encountered disaster but to improve the resilience of communities to face and withstand future disaster events. BBB represents adopting a holistic approach toward recovery by addressing risk reduction of the built environment, psychosocial recovery of affected people, and rejuvenation of the economy in an effective and efficient manner. Risk reduction can be achieved primarily through the improvement of structural designs in buildings and infrastructure and through better risk-based land-use planning. BBB requires improved building codes and land-use plans to be enforced using a strong legal framework along with financial backing to encourage adoption. Quality assurance of the rebuild is also integral for building back better.

Psychosocial recovery needs to be addressed to assist communities with moving forward with their lives as an important part of overall community recovery. Psychosocial recovery of affected people needs to be assisted through the provision of support services such as personal case management, counseling, and social activities. Inclusion of community members in recovery activities is another way to support psychosocial

recovery and provide recovery solutions that are in-line with community needs as part of building back better.

Economic recovery is essential for the recovery of communities. An informed economic strategy to address and support community-specific issues is the first step toward BBB-based economic recovery. Financial assistance, training, and business rebuilding support need to be provided to assist with economic recovery.

Reconstruction and recovery requires effective management of stakeholders and the use of post-disaster legislation and regulation in order to build back better. The creation of a recovery authority to allocate roles and coordinate and manage stakeholders is recommended. Successful recovery requires local-level partnerships and contribution to provide locally viable recovery solutions. Compliance of BBB-based concepts in recovery needs to be ensured through the use of appropriate post-disaster legislation and regulation to enforce risk reduction and community recovery initiatives. Legislation and regulation can also be used to facilitate post-disaster recovery activities by fast-tracking and exempting normal procedures.

The effective implementation of risk reduction and community recovery initiatives concurrently will result in building back better. Recovery efforts also need to be monitored continuously through short-term and long-term recovery to ensure compliance with BBB concepts and to obtain lessons to improve future disaster management efforts.

Build Back Better: The Way Forward

Understanding and implementing the concept of Building Back Better is integral to improving a community's resilience following a disaster event in order to achieve positive changes for affected communities. The elements required to build back better which are; risk reduction, psychosocial recovery, economic recovery, effective implementation and monitoring and evaluation, have been introduced and discussed in this chapter. This understanding can be used to create

practical guidelines to design future reconstruction and recovery efforts including all these key facets to effectively build back better. Further comprehension of how these strategies for building back better can be more successfully implemented in different environments can be gained by studying different disaster events in the future. It is also suggested that criteria for measuring levels of resilience should be established which can serve as indicators to measure progress and effectiveness of build back better practices.

The long-term sustainability of resilience in communities instilled by using BBB concepts depends on how they are linked with on-going developmental strategies. It is therefore important for the key concepts identified in this chapter to be incorporated into local and national government policies for community planning and development even during non-disaster periods.

Introduction

Selected key elements of modern seismic codes are reviewed here, along with a brief review of their historical development. What can be considered a single seismic code pertaining to a nation or a subdivision thereof consists of dozens of pages of provisions and by reference includes thousands of pages of standards that relate to loads, testing procedures, manufactured

building products, and materials. As used in this general discussion, “code” includes these other documents. Thus, it is far beyond the feasible scope here to provide an encyclopedic review of current seismic codes. Instead, this contribution is an attempt to delineate key features of most modern seismic codes and trace the development of their underlying concepts as they have evolved through the decades.

Preparing a global review of seismic codes runs the risk of turning out to be country specific and omitting other important references or milestones. This entry will attempt to avoid that. Instead the narrative will describe what a code should look like and what its important elements should contain. A building code places legal requirements on designers and constructors. Codes that fail to keep up with technological change and the advancement of knowledge become irrelevant. Building codes must be revised frequently, often at about 3-year increments. As more earthquakes occur and related building performance is observed, and as more research is conducted, the seismic provisions of a code often are one of the sections that change the most from one edition of a building code to the next.

The main purpose of building codes is to protect public health, safety, and general welfare as they relate to the construction and occupancy of buildings and structures. The building code becomes law of a particular jurisdiction when formally enacted by the appropriate governmental or private authority. The parts of a building code that relate to special requirements that must be fulfilled in order to inject a desired level of protection against the effects of ground shaking are called a seismic code. This broad description applies also to other types of construction, e.g., bridges, water tanks, towers, and port facilities. There are often additional codes or sections of a building code that have more specific requirements that apply to particular occupancies, for example, providing simplified requirements for the typical dwelling and more extensive requirements for the school, theater, or hospital.

Overview of Model Codes

A model building code is a convenient resource that can be adopted by the appropriate jurisdiction as its legal requirement. This makes the cost of maintaining and updating a code more economical and also provides design and construction consistency from one city to the next than would be the case if each developed its own code. That multiplicity of codes in a country was the rule throughout the nineteenth century and in many cases has only gradually trended toward nationally uniform provisions in the twentieth century. Two important interests that have pushed for uniformity are the construction and building materials industries, which can operate more efficiently if they have one set of rules, and the insurance industry, which desires up-to-date code provisions that can be easily evaluated for rate-setting purposes.

The practice of developing, approving, and enforcing building codes varies considerably among nations. Several countries have adopted model codes, including earthquake regulations, on a national basis, such as Japan, New Zealand, and Italy. In such countries, building codes are developed by the government agencies or quasi-governmental standards organizations and then made to apply across the country by the central government. Until 2000, the United States had three major model codes and associated seismic regulations, and even after their integration into the International Building Code, the process of adopting and enforcing the regulations, sometimes with significant variations, is left to the states and local governments. Similarly, in India each municipality and urban development authority has its own building code, which is mandatory for all construction within its jurisdiction. In Europe, the Eurocode is a pan-European building code that has all but superseded the older national building codes. Each country must now develop its own “national country annex” to localize the contents of the Eurocode. The seismic component of the Eurocode is only one small part of that model code. While the consistency of the regulations across European national

boundaries provides a better technical basis for its seismic and other provisions, the more important motive for such a code of European scope is economic. The Euro economic block can compete more effectively against the nations outside it if its design, construction, and building materials industries are guided by consistent provisions.

Prescriptive and Performance-Based or Objective-Based Codes

Building code requirements are usually a combination of prescriptive requirements that spell out exactly how something is to be done, on the one hand, and performance requirements that just outline what the required level of performance is and leave it up to the designer how this is achieved, on the other. An example of the former would be a rule of thumb for spacing of anchor bolts in house construction; an example of the latter would be to have the engineer calculate interstory drift and then design concrete cladding to accommodate that building-specific distortion. In recent years there has been a move among many building codes to move to more performance requirements and less prescriptive requirements. Performance-based code requirements still require tight definitions so that adequate performance can be evaluated by the building regulatory agency. The fire protection field has developed performance-based design approaches for many years, in which test or other data can be used to provide alternate means of fire protection instead of following the prescriptive requirements of a code.

In recent years, several countries, beginning with Australia, have moved to much shorter objective-based building codes. Rather than prescribing specific details, objective-based codes list a series of objectives all buildings must meet while leaving open how these objectives will be met. When applying for a building permit, the designers must demonstrate how they meet each objective. This makes it necessary for approving authorities to employ correspondingly qualified personnel so that a productive synergy can be

created between innovative designs and traditional safety concerns. It also requires a high degree of professionalism, because it gives the architect and engineer more leeway, as compared to more prescriptive requirements, and also requires a higher level of building code enforcement review. Seismic isolation, inclusion of damping devices, response history analyses, and displacement-based design are some of the innovative approaches currently in use in some places where this higher level of design and review capacity is present. Each of these represents challenges in analysis and design that require an intimate knowledge of the underlying mechanics-based mathematical theory and its limitations. As such, they are best performed by professionals with considerable experience because there are alternative approaches that require deep insight on the part of the engineer.

Seismic codes begin with the goal of providing safety, and many stop there in most respects, but some include requirements for protecting the functionality of essential buildings, such as fire stations, hospitals, and emergency communications centers or data processing centers. This is discussed in the separate chapter on Essential Facilities and is only mentioned in passing here. Some of the most stringent regulations of this type were passed in California after the 1971 San Fernando Earthquake, when the Hospital Seismic Safety Act of 1972 was passed. The Veterans Administration adopted its own regulations after that earthquake, regulations that seek to not provide not only safe hospitals but also more functional ones. Some voluntary above-code ("performance-based design") approaches lead an owner to invest in the cost of greater seismic protection to achieve less property damage in earthquakes, but the most common seismic design criteria that go beyond the goal of providing safety are related to protecting essential functions.

Geologic and Geotechnical Topics

Mentioned briefly here are geologic and geotechnical engineering aspects to the seismic

provisions of a building code. Construction regulations that deal effectively with earthquake vulnerabilities must include within their purview geologic hazards such as surface faulting and liquefaction. Geologic and geotechnical engineering provisions to deal with those hazards came later than structural provisions. In 1972, the state of California passed the Alquist-Priolo Fault Zoning Act (the current name, which has changed over the years), and slightly before that the city of Portola Valley, which is bisected by the San Andreas Fault, passed its own legislation. Surface fault zoning is the most clearly delineated of the earthquake ground failure hazards, and thus it was logically the first to be subject to regulations. Liquefaction was not a word that soils engineers (then the term for geotechnical engineers) used prior to the 1964 Alaska and the closely following 1964 Niigata Earthquake, but in the following decades, areas of a jurisdiction that were suspect in terms of poorly compacted granular soils and high water table were frequently zoned as requiring special geotechnical investigations. Geotechnical engineers now have at their disposal field and laboratory investigation techniques and a knowledge base about how soils behave in earthquakes that did not exist in the 1960s. Codes and standards of practice can now require geotechnical evaluations that would have been impossible to perform a few decades ago.

One tool that developed out of non-seismic slope stability concerns that later was seen to have a seismic benefit is the grading ordinance. The city of Los Angeles passed such a law in 1952 controlling how excavation and cut and fill could be performed. Such ordinances have become common, and the geotechnical engineering evaluations required in the design stage now typically include earthquake considerations in regions where a seismic code is enforced as well as non-seismic landslide hazards.

Nonstructural Code Provisions

Coming later than structural regulations were provisions to protect the nonstructural features of a building. The first detailed report on

earthquake nonstructural damage was done for the 1964 Alaska Earthquake (Ayres et al. 1973), with a similar report on the 1971 San Fernando Earthquake (Ayres and Sun 1973). Nonstructural provisions are only briefly mentioned here but are an essential part of the modern seismic building code. Approximately three-quarters of the initial value of a modern building's construction, dwellings excepted, is composed of nonstructural components, such as enclosure systems, elevators, partitions, fire sprinklers, ceilings, and heating-ventilating-air-conditioning equipment. In general it can be said that the leading seismic codes of the world have increasingly included more and more detailed regulations for the calculations of loads that are used to design nonstructural bracing and anchorage, but a lack of coordination of the implementation of these rules still persists. Different design professionals work on their own systems – architects on partitions and ceilings, fire protection engineer on fire sprinkler system, mechanical engineer on the HVAC system, and so on – and yet it is the structural engineer with the most expertise for such work. And then different contractors and trades work on the implementation phase, often with little guidance or oversight. Recent earthquakes have demonstrated that simply having nonstructural damage protection rules on the building code's books is not sufficient to actually protect that myriad of components. A common example is that some codes for many years have contained a clause stating that nonstructural components must be designed for the motions and deformations that the structure imposes upon them, but in actual practice, partitions and other components were constructed without this engineering.

Historic Context

Some accounts of historic building code evolution claim that the Code of Hammurabi (a Babylonian king of some 3,800 years ago who was considered by his subjects to be a god as well) engraved on stone is the first building code ever to have been put into effect. That notion needs to be dispelled because the Code

of Hammurabi is much more of a civil or penal code as it has only a few articles out of several hundreds that even mention buildings. It has harsh penalties for builders of shoddy buildings, but the rest of the provisions are divine orders that deal with the trade of commodities, sale of slaves, marriage unions, inheritance regulations, and the like. King Hammurabi informs a builder that if the house he builds should collapse and kill the person who owns it, then he too stands to lose his life, but there is no explanation for how one might build a house that does not collapse. Thus, it fails the test of belonging to the family of codes because it has no stipulations for how things should be done; only penalties are listed that must have been intended to discourage negligence of good building practices.

Tobriner (1984a) provides a historical survey of the development of building codes, noting that they originated primarily in the form of fire-resistant construction requirements, and then only much later in most countries had seismic regulations added to them. The first systematic national building standard was the London Building Act of 1844. Among the provisions, builders were required to give the district surveyor 2 days' notice before building, and they contained regulations regarding the thickness of walls, height of rooms, the materials used in repairs, and the dividing of existing buildings. The placing and design of chimneys, fireplaces, and drains were to be enforced, and streets had to be built to minimum requirements. The city of Baltimore passed its first building code in 1859. The Great Baltimore Fire occurred in February, 1904. Subsequent changes were made that matched the contemporary fire-resistant regulations of some other large American cities. In Paris, under the reconstruction of much of the city by Baron Haussmann during the Second Empire (1852–70), great blocks of apartments were erected, and the height of buildings was limited by law to six stories. Though height limits were instituted for city planning reasons, they later sometimes became part of seismic codes in determining allowable structural systems for various heights.

Construction Regulations Preceded Engineering Regulations

A historic survey of prescriptive requirements on how to build for better seismic performance shows that these landmarks were always reached after cataclysmic experiences. These early regulations, such as were passed after the 1509 Istanbul Earthquake, 1755 Lisbon Earthquake, or the 1880 Luzon (Manila) Earthquakes, were limited to descriptions of allowable building materials and building heights. They predated the extensive use of reinforced concrete and steel. Unreinforced masonry was an allowable material in these early regulations, and no quantitative method was provided for calculating either demands or capacities. Thus, they are primitive seismic codes in today's light, regulating some features of construction but not employing the quantitative methods civil engineers would later develop. That notwithstanding, these efforts are impressive for making such early attempts to improve the building stock's earthquake resistance.

The major earthquake that shook Istanbul in the summer of 1509 led to the banning of stone masonry construction in the city, because most deaths had occurred when such buildings collapsed. This decision paved the way for the emergence of another form of disaster that plagued the city for the next four centuries: fires consumed not only timber construction but also much of the cultural heritage. Following the 1755 earthquake in Lisbon, which destroyed the city center area known as Baixa, the Marquis of Pombal gathered a group of builders to determine the best manner of earthquake-resistant construction to use for the rebuilding. The type of construction selected became known as the Pombalino wall. In its complete form, it is also referred to as "gaiola" or "cage" construction. Most, if not all, of the buildings reconstructed in the reconfigured planned Baixa area were constructed with Pombalino walls and sometimes (but not always) with complete "gaiola" timber frames (Tobriner 1984b; Langenbach 2003).

The Pombalino system was not based on what today would be known as rational methods of

analysis, applying engineering theory to a given case and calculating loads and resistances. It was an attempt at earthquake-resistant construction, not earthquake engineering per se, because the engineering techniques of the nineteenth and twentieth centuries were far off in the future. It was decreed in royal fashion for use in a city that had experienced one of the most destructive earthquakes in Europe and was based on the construction tradition in the Mediterranean basin and may have borrowed construction lore developed by shipbuilders. It was used on the interior of buildings that consisted of timber frames with vertical and horizontal timbers of approximately 10–12 cm square, with internal braces, forming an “X,” referred to in Italy and Portugal as the “Cross of St. Andrew.” The timbers for the cross were 9 cm by 11 cm in section. The frame was then “nogged” (i.e., filled with brick) in the triangular spaces formed by the crosses with a mixture of stone rubble, broken brick, and square pieces of Roman brick in different patterns in each panel. The interior walls were then covered with plaster, hiding the infill and the timber frame. The exterior facades of the Baixa buildings were reconstructed with load-bearing masonry walls of about 60 cm in thickness, some of which had a timber frame on the inside face (Gülkan and Langenbach 2004).

The 1906 San Francisco Earthquake was something of a nonevent in the history of seismic codes. Although the cause of the earthquake was accurately noted – the San Andreas Fault had been mapped in several areas before the earthquake and its surface rupture was well documented afterward – and although civil engineers trained in universities were in existence, no engineering consensus existed around provisions that would define how to calculate loads and then calculate the lateral resistance of a structure. Unreinforced masonry was not prohibited, and by the time the city took stock of its unreinforced masonry building seismic hazards in the 1980s, over 90 % of the 2,000 buildings that required retrofitting were dangers that were built after the earthquake, not before it. The San Francisco building code even reduced the wind load a few years after the earthquake. In that era, the wind

load was sometimes thought to be a surrogate for seismic load.

A few years later, after the 1910 Cartago Earthquake in Costa Rica, a national code was passed that phased out adobe and trapia (rammed earth) structures, substituting bahareque construction (sawn lumber or bamboo framing with plaster). This was a similar but more regulatory approach to the substitution of wood for masonry that occurred in construction styles after some other earthquakes, such as the 1855 Wairarapa (Wellington, New Zealand) Earthquake.

The First Seismic Codes with Engineering Content

Soon after the 1906 California Earthquake, the 1908 Messina-Reggio Earthquake occurred in southern Italy, but it had a different and more beneficial impact on building codes. Sorrentino (2007, 2011) relates how a committee of engineers developed an equivalent lateral force analysis method that was adopted into the building code of the disaster region. It even had the refinement of applying a different lateral force coefficient (*rapport sismica*) to the ground story (1/12) than the story above (1/8), accounting for greater acceleration in the second or third stories. After the 1915 Avezzano (or L’Aquila) Earthquake, the code was changed to have factors of 1/8 for the ground story and 1/6 for the upper stories. These Italian seismic provisions applied only to the area affected by the earthquakes, a pattern that was common in early codes prior to the availability of national maps depicting the hazard of seismic ground shaking.

At the turn of the nineteenth to twentieth century, Riki Sano was getting his PhD from the University of Tokyo on “Seismic Design Concept for Building Structures,” along with Tachu Naito, his student; Sano was to be instrumental in the development of the Japanese equivalent lateral force method. Their work came to fruition after the 1923 Great Kanto or Tokyo Earthquake of 1923, when the 1924 Urban Building Law Enforcement Regulations were passed. It used a 10 % lateral force factor (*shindo*) applied

uniformly up the height of the building. As an example of how engineering practice in some cases is in advance of the codes, when the 1923 earthquake occurred, three large buildings designed by Tachu Naito had already been built (and performed well in the earthquake, giving the new equivalent lateral force method a boost into the code).

An important threshold was crossed in Japan toward the implementation of scientifically determined national seismic provisions (Otani 2008). The objectives of the Japanese Building Standard Law, proclaimed in May 1950, were “to safeguard the life, health, and properties of people by providing minimum standards concerning the site, structure, equipment, and use of buildings.” The law outlined the basic requirements, and the technical details were specified in the Building Standard Law Enforcement Order (Cabinet Order) and in a series of Notifications by the Minister of Construction.

The seismic design provisions of the Building Standard Law Enforcement Order were significantly revised in 1981, including the following three major changes:

1. Structural calculations are required to examine (a) maximum story drift under design earthquake forces, (b) lateral stiffness distribution along the height, (c) eccentricity of mass and stiffness in plan, and (d) story shear-resisting capacity at the formation of a collapse mechanism.
2. Earthquake resistance is specified (a) in terms of story shear rather than horizontal floor forces, (b) as a function of fundamental period of a building and soil type, and (c) separately for the allowable stress design and the examination of story shear-resisting capacity.
3. Required story shear-resisting capacity is varied for construction materials and with the deformation capacity of hinging members under earthquake forces.

The framework of the law was also significantly revised in 1998, (a) introducing performance-based regulations wherever feasible, (b) allowing private agencies to execute the

building confirmation and construction inspection works, (c) deregulating urban land use, and (d) allowing public survey of design and inspection documents. New technical specifications in the form of the Law Enforcement Order and a series of Notifications of the Minister of Construction were issued in June 2000, including the definition of performance objectives at design limit states and the specifications for verification methods.

California’s contribution to the development of the modern seismic code based on engineering calculations had a small start after the 1925 Santa Barbara Earthquake, and then after the 1933 Long Beach Earthquake, statewide regulations were passed that were derived from the Japanese code. The 1930s was the decade when the lineage of seismic codes in several countries began. Provisional earthquake regulations were enacted in Chile in 1930 after the Talca Earthquake and became more institutionalized after the 1939 Chillán Earthquake. In New Zealand, following the 1931 Hawke’s Bay Earthquake, the 1935 New Zealand Standard Model Building By-Law included earthquake regulations. India adopted its first seismic code in 1935 following destructive earthquakes in 1931 and 1935 in Quetta (now part of Pakistan), and the 1939 Erzincan Earthquake in Turkey led to its first engineering regulations for the earthquake hazard.

Equivalent Static Elastic Lateral Force Method

A seismic load on a building is actually dozens of different significant seismic loads that occur during the 20–60 s during which the ground is strongly shaking. The earliest practical way to “put a number” on that bewildering set of loads, which are not well known in advance of the earthquake, was to represent the worst loading effect as a percentage of the weight of the structure, recognizing that seismic shaking causes inertial loads, and inertia is a product of mass and acceleration. The full descriptive name of the method is the equivalent static elastic seismic lateral force analysis method. It is intended to be

equivalent to or adequately represent the actual earthquake forces; the method computes a single static force to represent the changing dynamic forces; that force is applied to an analytical structural model that remains elastic, even though inelastic behavior obviously occurs; and it is an analysis method for determining only the design loads, not for distributing them through the structural components and connections that provide the resistance to the loads. And finally, the only design loads were lateral or horizontal, whereas strong motion records routinely measure some vertical motions as well. Each of these limitations was to be worked on in the following decades. From these first incarnations, the equivalent lateral force method was refined to include several necessary considerations.

Instead of applying seismic regulations to a region after it had an earthquake, earth scientists compiled maps showing where earthquakes should be expected. This was first done with a small number of large-scale zones for a country, each zone defining the force factor to be applied. Then beginning in the 1950s in Japan, a probabilistic basis to the maps was developed. Kawasumi (1951) developed three maps, depicting the shaking that should be expected to occur in exposure periods of 75, 100, and 200 years. The Applied Technology Council in its ATC-3 document (Applied Technology Council, 1978) included national maps produced by S.T. Algermissen that had a probabilistic basis. In China in 1977 a national seismic design map was based on shaking with 3 % and 10 % probabilities of being surpassed. Formats such as these for tying the probability of occurrence to the severity of shaking have become standard in seismic codes today. Another refinement has been microzonation: zoning small areas as having different ground shaking severities, or ground failure hazard (e.g., liquefaction), based on local soils. It became increasingly known that in general soft soils amplified ground shaking, though the large differential response between soft and hard grounds as measured in low-level shaking was not found to be linear up through high levels of ground motion: a column of soft soil 30 m high simply cannot move back and forth rapidly

enough to track rapid and severe motion of the underlying strata, and soil can behave nonlinearly just as structural materials do. The limiting case of microzonation is the site-specific evaluation, where the construction to be placed on a site is designed for a customized set of earthquake criteria, a more expensive approach usually reserved for major facilities.

On the structural side, knowledge of different structural systems and materials had to evolve for codes to seismically regulate them, and a growing body of structural laboratory research provided that information. The steel and concrete industries in particular were the settings for a large amount of research conducted in the 1950s and later. Research on reinforced concrete in great part conducted at the University of Illinois was the technical basis for an important document that advanced the use of that material in seismic codes (Blume et al. 1961). The other kind of research that provided this knowledge was actual earthquake performance. Earthquake reconnaissance or field surveys of the effects of earthquakes became increasingly common in the 1960s.

The early codes provided loads computed with a slide rule that were low enough to keep the structural model that was on the engineer's drawing board in the elastic range. (Computers did not become widespread in seismic design or other civil engineering practice until the 1970s.) Slowly, inelastic behavior was included in codes by including requirements for ductility. Classifying structural systems and materials was an approximate first approach. A structure thought to have greater ductility was designed for lower elastic-level forces, because there was confidence in how it would perform when pushed into the inelastic range. The ability of ductile connections and members to absorb punishment without failure, and also the softening effect (period lengthening) and its beneficial effect on response, became increasingly recognized in the 1960s, 1970s, and 1980s. Today, the choice of a structural system is heavily influenced by how the code defines its ductility. Seismic structural codes are all aware that ground motions are random and can be determined only approximately

in advance. For this reason they contain provisions to prevent unexpected surprises leading to catastrophic failures. Lessons that have been taught by past earthquakes for how building components behave under ground shaking are embedded in their verbiage. As theory and experiment combine to lead to more refined ways of seismic protection, this knowledge must be incorporated into the newer versions of codes for continuous improvement.

The Response Spectrum Method

Yet another improvement in seismic codes was consideration of the dynamic properties of the structure, its period or periods of vibration, and the amount of damping. The tendency of the structure to respond at its natural frequency was only useful information if the frequency content of the ground shaking was also known: in structural dynamics, it takes two to tango. Because the first strong motion seismograph (accelerograph) was only deployed in 1932, it took years for records to accumulate to provide a statistical picture of earthquake severity in terms of frequency content. Trifunac (2006) traces the history of the response spectrum method of analyzing earthquake ground motions and producing design spectra that engineers could use to proportion required resistance of the structure. Two of the most influential developers of the method were Maurice Biot and George Housner, whose doctoral theses at the California Institute of Technology (1932 and 1941, respectively) were devoted to this topic. The theory became widely applied in engineering practice in the 1970s and 1980s when several conditions were favorable. First, there were more earthquake records. Second, engineers could afford to have the new, more powerful electronic computers on their desks that could do the extensive mathematical work. Housner (1997, p. 33) notes a third factor: "Because of the practicing engineers' reluctance to employ the design spectrum, I think it was essentially the nuclear power business that got the spectrum into widespread use."

Concerning the growing number of earthquake records, the city of Los Angeles played an important role when it passed a revision to its building code in 1965 requiring that three strong motion instruments be installed in buildings six stories or taller (one at the base, one at mid-height, one at the roof). This resulted in the large harvest of ground motion and structural motion records from the 1971 San Fernando Earthquake. The city of Los Angeles also was precocious in its 1943 adoption of a formula in its code that related period of vibration as represented by number of stories to the base shear coefficient calculation in its equivalent lateral force method: the taller the building, the lesser the base shear. In 1957, Los Angeles also had a strong effect on the development of earthquake codes, even though it was not an earthquake code revision: the zoning code was revised to allow buildings taller than 150 ft. Engineers in California thought that taller, more flexible (longer period) buildings could be designed for lower force coefficients, and they also knew that if the same coefficients as were used for low-rise buildings (typically 10 % to 13 %) were applied to every story in a tall building, the large amount of strength, and thus area taken up by shear walls and other structural material, would have very negative architectural and real estate implications.

When it seemed that engineers in the two large urban regions of California, centered on Los Angeles in the south and San Francisco in the north, could be diverging toward significantly different provisions for dealing with the tall building question and the modernization of seismic codes, the statewide structural engineering organization Structural Engineers Association of California (SEAOC) began its influential set of editions of the "Blue Book," the *Recommended Lateral Force Requirements and Commentary* (SEAOC 1959). Its requirements became the seismic provisions of the Uniform Building Code used in various editions and adaptations throughout California and the Western United States until the year 2000 when the UBC was folded into the IBC, as previously described.

The Response History Method

The equivalent static lateral force method leads the engineer to calculate a single quantity, the total shear at the base of the building, the base shear, and then proportion that load up the height of the structure according to procedures that attempt to represent the dynamic response of the building in a simple way. While there is dynamic thinking underlying the method, it still represents the series of motions that occur during the earthquake with a static view or “snapshot” of the overall effect of those motions. The response spectrum method similarly is a way to give the engineer a base shear to use in design. A given overall representation of one record, for example, the peak ground acceleration, might exceed that of another record and yet that other record might be more damaging to a particular structure. A record with greater duration, more pulses above a threshold such as the elastic limit of a portion of the structure, can create more demand than a record of smaller duration, even if the latter has a greater peak value (Johnson 2013). The logical improvement was seen to be to calculate the various forces and deformations that occurred to a structural model split second by split second in response to the changing ground motion.

Three sources of research information that developed from the 1960s to the present day provided the basis for incorporating a fully dynamic method into seismic codes, subjecting the analytical model of the structure to the motions of several recorded earthquakes. One came from completely outside the earthquake engineering field, the development of the modern computer. A second prerequisite was a large library of earthquake records, conveniently supplied by growing coverage of highly seismic areas with strong motion instruments and, unfortunately, by Earth’s frequent earthquakes. The third was improved knowledge of structural behavior, in particular of how structures behaved in the inelastic range. While computers played a role in that research on structural behavior, it has also required the traditional approach of subjecting specimens to simulated seismic loading in the laboratory. Computer simulation is not

capable of substituting for the simulation of physical testing.

A 1973 benchmark for the development of the response history method is provided by the seismic design manual of the US military (Departments of the Army, the Navy, and the Air Force 1973, pp 3–3): “Since the mechanics of dynamic analysis requires that a separate solution must be obtained for each instant of time during the entire history of interest, computation by computers is necessary. This kind of analysis is generally beyond the kind of effort that can be afforded in the design of almost all but the most critical structures.” Today, the method is more frequently used, though it still is applied to a small minority of all the structures being seismically designed. Chopra (2005, p. 107) provides an assessment of the future of the method:

At the present time, nonlinear RHA [response history analysis] is an onerous task, for several reasons. First, an ensemble of site-specific ground motions compatible with the seismic hazard spectrum for the site must be simulated. Second, despite increasing computing power, inelastic modeling and nonlinear RHA remains computationally demanding, especially for un-symmetric-plan buildings—which require three-dimensional analysis to account for coupling between lateral and torsional motions—subjected to two horizontal components of motion. Third, such analyses must be repeated for several excitations because of the wide variability in demand due to plausible ground motions, and the statistics of response must be considered. Fourth, the structural model must be sophisticated enough to represent a building realistically, especially deterioration in strength at large displacements. Fifth, commercial software is so far not robust enough to predict response with high reliability. Sixth, an independent peer review of the results of nonlinear RHA is required by the FEMA-356 guidelines, adding to the project duration and cost. With additional research and software development, most of the preceding issues should be resolved, and nonlinear RHA may eventually become the dominant method in structural engineering practice.

Growth in Adoption of Seismic Codes

Figure 1 provides a quick way to see how seismic codes have spread from an initially small number of countries. The numbers are drawn from the

Building Codes and Standards, Fig. 1 Growth in the adoption of seismic codes (Reitherman 2012, p. 582)

various editions of *Regulations for Seismic Design: A World List*, published by the International Association for Earthquake Engineering (1960 and later editions).

One could argue that because seismic codes now cover most of the significantly seismic areas of the world, seismic safety has now been achieved on a global scale. This would be overly optimistic for two reasons. First, there are always older, pre-code buildings that did not benefit from a modern seismic code. Secondly, even today in countries with regulations “on the books,” legally binding laws that include the latest earthquake engineering thinking, those regulations are not always thoroughly carried out.

The seismic provisions in a code must be complemented with reliable implementation of the code, its effective enforcement. This remains one of the hardest issues to solve, especially in poorer countries but also in the most developed. Merely making seismic codes more sophisticated as each new edition is promulgated every few years is not a solution, unless comprehensive implementation also occurs. This includes the education and professional training of the engineers and other design professionals involved as well as the thoroughness of the quality control measures of building regulation agencies, such as in the plan review and construction inspection phases. In some instances, the comprehensive protection that the provisions in a building code seem to provide exists mostly on paper. Up until the 1990s, even the most advanced seismic codes

listed only a few specific nonstructural components that needed anchorage and then added a general phrase such as “all other equipment and machinery.” That sounds comprehensive, but in the absence of a well-defined definition of that all-encompassing phrase, it was not particularly meaningful. Another example is the accurate calculation of interstory drift, which in some codes was seemingly covered many decades ago but in practice was not well-implemented in standard practice. The engineer who diligently tried to meet that code requirement had inadequate analytical tools available because of the lack of underlying knowledge of the displacements that would actually occur. Conversely, some engineers incorporated design measures that were only required by the code much later. In the words of George Housner (1986, p. 25), “in some instances, earthquake requirements were adopted in building codes but were not used by architects and engineers. And in other instances earthquake design was done by some engineers before seismic requirements were put in the code.”

Summary

Model building codes are common around the world, although the consistency with which they are applied throughout a jurisdiction can vary greatly. In New Zealand and Japan, there is a high degree of consistency in how a nationally

standardized set of seismic provisions are adopted and enforced at the local level. In India and the United States, there is greater variation. Seismic provisions in model building codes are usually a combination of prescriptive and performance-based procedures. Seismic provisions in building codes evolved from the earlier building codes that were typically motivated by concern over fire resistance and urban conflagrations. The first seismic regulations governed construction characteristics such as wall material or number of stories, but because they preceded civil engineering developments of the 1800s and 1900s, they lacked quantitative methods for calculating loads and capacities. In the early 1900s, the first seismic codes based on engineering methods were developed in Japan and Italy. The equivalent static elastic lateral force method originated in these codes. By the 1930s, seismic regulations based on the equivalent lateral force method were adopted in New Zealand, the United States, Turkey, India, and Chile. Later, as earthquake engineering research accumulated, as strong motion records were collected, and as powerful and inexpensive computers became available, the response spectrum and the response history methods were added to the modern building code's seismic provisions. A fundamental problem in reducing earthquake risks through adoption of up-to-date building code provisions is enforcement and implementation. While the problem is most prominent in poorer countries, it is also an issue in the most technologically advanced areas of the world. It is to be expected that displacement-based procedures will make further inroads into routine structural system analyses. Also, as seismic isolation technology becomes more mature, it will be accepted by more owners on account of observed benefits.

Earthquake damage mapping; Object-oriented classification; Very high-resolution SAR and optical images

Introduction

During a seismic event a fast and reliable damage map of the urban areas involved is very important to manage civil protection interventions. Satellite remote sensing data can provide valuable pieces of information in this respect, thanks to their capability to have an instantaneous synoptic view of the scene especially if the seismic event is located in remote regions or the main communication systems are damaged. The major limitation that could hamper the operational use of this source of information is the speed of data collection just after a disastrous event. This is a key point for civil protections that need a fast overview of the epicentral area, quick information on to the extension and distribution of damages and the evaluation of infrastructure conditions such as roads, bridges, focal and crucial buildings and so on. A single satellite can provide access time to a specific site in the order of days as a result the necessity to use any kind of available satellite image and making mandatory data integration approaches to increase the chance of collecting information in near real time (Chini 2009).

Since the end of the twentieth century satellite systems and image-analysis techniques have progressed a lot in the aspects where they can contribute significantly to support the

management of major natural disasters, as well as humanitarian crisis situations. Compared to 15 years ago the availability of satellite imagery, amount, timeliness and the capability to cover a certain crisis situation or disaster event with high degree of detail have all improved substantially. There are several factors which have led to this. First of all ground pixel spacing of civil Earth Observation (EO) systems has developed to the meter domain (or less) for optical and radar systems, such as synthetic aperture radar (SAR) (Voigt et al. 2007). Indeed on September 24 1999 the commercial EO satellite IKONOS was launched, the first able to collect openly available high-resolution imageries that were both panchromatic and multispectral with a spatial resolution of 1 and 4 m, respectively. Two years later, on October 18, 2001, another important step forward was made with the launch of one more high-resolution commercial EO satellite, QuickBird, with an increased spatial resolution up to 0.6 m for the panchromatic sensor and 2.4 m for the multispectral one. The first earthquake where this kind of data proved its usefulness in conjunction with automatic image-analysis techniques was the one that struck the city of Bam (Iran) in 2003, provoking a lot of damage to man-made structures and causing the death of many people (Yamazaki et al. 2005; Gusella et al. 2005; Stramondo et al. 2006; Gamba et al. 2007; Chini et al. 2008b; Chini et al. 2009; Bignami et al. 2011). Concerning SAR satellite sensors, the spatial resolution breakthrough arrived in 2007 with the launch of the first two satellites of the two X-band satellite constellations, COSMO-SkyMed and TerraSAR-X, on June 8 and on June 15, 2007, respectively, both having the capability to acquire images in the so-called SpotLight image mode with a spatial resolution of 1 m. TerraSAR-X mission is composed of two satellites, the second one was launched on June 21, 2010, while COSMO-SkyMed has four satellites, the fourth one launched on November 5, 2010. The fact that they are constellations has reduced the site access time down to two and a half days with TerraSAR-X and to 12 h with COSMO-SkyMed. This latter issue is the second

important factor that makes satellite data able to face and provide useful information during the crises phase soon after an earthquake.

Both optical and SAR data have characteristics to be used as a source of information to provide a damage map after an earthquake (Yonezawa and Takeuchi 2001; Matsuoka and Yamazaki 2004; Chini et al. 2008a; Chini et al. 2013), with particular attention to very high-resolution data, which has the potential to monitor wide areas, but at the same time giving information on single structures present in the scene (Stramondo et al. 2008; Turker and Sumer 2008; Brunner et al. 2010; Chini et al. 2011; Dell'Acqua et al. 2011; Ferro et al. 2013). The huge amount of information carried by these kinds of data can hamper the visual inspection, which is time consuming during a crisis phase, fostering the implementation of more automatic approaches.

Methodology

The automatic or semiautomatic classification of remote sensing data is a tool to help understand and monitor a large variety of scenarios, converting them into tangible data, which can be utilized in conjunction with other data sources to provide crucial and accurate information. Even if metric or submetric resolution images provide new opportunities in the damage mapping field, new problems arise at the same time in automatic classification procedures. Indeed, the aim of image classification analysis is to extract information and display the results in a simple and effective way for possible further studies. In metric resolution images a single pixel represents a small area ($0.5 \div 10 \text{ m}^2$) of the acquired scene and is usually smaller than the size of the objects of interest. Hence the information of a single pixel is strongly linked to the information carried by its neighbors, which are part of the same object, pointing out the necessity to perform an object-oriented analysis, although the measureable statistics typically exploited for classification purposes are necessarily pixel

based (Blaschke 2010). This aspect is very interesting, because it makes possible to focus on a single object, for example, a building or also other man-made structure, having the advantage of a valuable amount of pixels to characterize the object itself.

Object-based techniques recognize that important semantic information is not always represented in single pixels but in meaningful image objects and in their contextual relations. For example, it is more likely that a pixel adjacent to a private garden should be classified as a house, road, or private garden rather than as a forest. Usually, object-based classification comprises two steps: the image segmentation and the object classification. Image segmentation subdivides the image into groups of contiguous pixels called objects or segments that correspond to meaningful features or targets in the field (Blaschke 2010). The images are segmented into homogeneous objects based on the spectral information and local patterns or textural information that are included in groups of neighboring pixels. As a result, the object-based classifications can consider a wide range of variables such as mean reflectance, texture, shape and size of objects and can potentially produce more accurate and detailed maps than conventional classification strategies (Mathieu et al. 2007; Blaschke 2010; Chini et al. 2014).

All algorithms exploiting metric resolution data for damage mapping purposes have to deal with object-oriented approaches even if the final target is not the object itself, but maybe just a classification useful for restricting the analysis and the statistics to classes we are interested in. Such an example could be a change detection approach to identify a collapsed building using one pre-earthquake image and one post-earthquake image by a threshold approach. At this resolution many regions will be affected by changes even those not relevant for damage purposes. Thus to fix the threshold used to identify damaged buildings (pixels that have changed their radiometric values because of the earthquake) we should restrict the analysis to objects of interest such as buildings (Chini et al. 2009).

It is worth recalling the optical and SAR image properties that are usually used for damage detection purposes, highlighting characteristics that are relevant to damage mapping analysis such as the physical properties of the measured signal and the spatial resolution that can have an impact on the final products. Basically, the process for forming a SAR image is different from that used for an optical image for two main aspects: the physical properties of the imaged targets that contribute to the measured signal and the signal processing steps used to create the image. Optical sensors measure the radiometric properties of reflected sunlight in spectrally distinct regions of the visual and near-infrared spectrum or integrated in a single panchromatic band. The material properties of objects, the illumination conditions of the scene and the sensor perspective determine the radiometric and geometric appearance of distinct targets in optical imagery. The SAR system is an active sensor and measures the backscatter of a transmitted signal, typically in a narrow microwave frequency band and sampled in the range direction, i.e., the line of sight (LOS) from SAR sensor to target. Backscattering is primarily determined by the geometry and dielectric properties of an object and the transmit/receive configuration of the SAR sensor (Brunner et al. 2010).

Concerning optical images it is easier for the reader to grasp how different spatial resolutions make buildings appear and more in general, cities, where if the resolution is higher, the amount of detail composing land use classes of interest will be greater. Indeed, in high-resolution optical images the radiance of each pixel is not directly related nor can be considered representative of the class it belongs to. However, many studies are able to demonstrate that the advantage of being able to aggregate pixels to an object and then address object characteristics, is that it can discern between different kinds of buildings and different kinds of asphalted areas such as roads or parking lots, turning all of this augmented complexity of understanding into an information luxury (Pacifi et al. 2009). Such an example could be the shadow from a building, which has at this resolution a clear signature in the image,

giving us information about the building height, which could be also an important source of information for damage detection purposes. As a matter of fact, Turker and Sumer (2008) detected damaged buildings from the big earthquake in Turkey in 1999, applying a watershed segmentation on a post-event optical image utilizing the relationship between the buildings and their shadows, labeling 80 % of buildings correctly as either damaged or undamaged. Another example of how object-oriented approaches are useful is presented in Gusella et al. (2005) that quantified the number of collapsed buildings of the Bam earthquake in 2003, starting from the inventory of buildings as objects in QuickBird satellite imagery taken before the event.

Pertaining to SAR data an in depth description of how a building appears is necessary. For this purpose, it is useful to describe how radar returns from different parts of the building are mapped on the SAR image due to the fact that they reach the receiver at different times (Kropatsch and Strobl 1990; Franceschetti et al. 2002; Franceschetti et al. 2003; Guida et al. 2008; Guida et al. 2010). Given an isolated building on ground and proceeding in the SAR image with a constant azimuth from near to far range, we can identify four main singular contributions:

1. A bright stripe corresponding to a mixture between the backscattering from the ground, facade, and roof, which is a typical example of layover in a SAR image. Layover is called “radar mapping,” where different object points having the same time and same range are mapped into one image point, i.e., more than one point on the Earth’s surface are mapped into one image point (many to one mapping). SAR mapping is mainly an integration of reflected signals having the same Doppler frequency (azimuth or along-track measurement) and same distance (range or across-track measurement) (Kropatsch and Strobl 1990).
2. A very bright line corresponding to facade-ground and ground-facade double-bounce scattering, because double-bounce ray paths all have the same length, equal to

the distance between SAR sensor and the facade base (all different scattering points are positioned at a unique distance, corner reflector).

3. The contribution from the roof that could be of two types: (a) flat roof, a unique gray area corresponding to backscattering from the roof, and (b) gamble roof, the roof has a different scattering signature with respect to a flat one. Basically it is different due to the presence of a second bright scattering feature, which is closer to the sensor than to the double-bounce contribution (Brunner et al. 2010). This behavior concerns only the direct backscattering from the part of the roof that is oriented toward the sensor.
4. A dark area corresponding to the SAR building shadow which should be not confused with the shadow concept in an optical image. Shadow in radar imagery is called the region where an object point is not reached by any radar beam. Such object points produce a “zero” signal in the image. Therefore, shadow regions appear as dark areas corrupted by noise (Kropatsch and Strobl 1990)

Of course this is a simplistic schematization of the phenomenon; other parameters also play an important role in the backscattering values of the four building parts such as geometric parameters (height, length, and width of the building and the roughness of the ground) and the electromagnetic parameters (dielectric constants of facade, roof, and ground). The four types of building responses with a distinct backscattering values can be detected as separate objects if the resolution is higher than the dimension of a building itself, while this distinction is not possible if the SAR resolution is lower than the buildings being identified. As a matter of fact an urban area imaged by a SAR sensor with a resolution in the order of tens of meters appears uniformly brighter than other land cover classes since the double-bounce effects are the dominant scattering component in the SAR resolution cell (i.e., the image pixel), that one characterizing the backscattering for such scenario. Whilst in metric resolution SAR sensors such as COSMO-SkyMed and

TerraSAR-X, we still have very bright values in the city, principally double-bounce pixels, but we have gray and dark regions as well, roofs and shadows respectively, that are well identified and with a remarkable spatial extension. On the contrary big uniform surfaces, such as bare soil or asphalted industrial areas, appear the same in both high- and low-resolution SAR since their extension is bigger than both sensor resolutions. Change detection approaches with lower-resolution SAR stem from the concept that the double-bounce effect fails when a building collapses (which is the dominating scattering mechanism in the resolution cell); thus in the comparison between two images, one acquired before and one after the seismic event, a decrease in the backscattering value is expected (Yonezawa and Takeuchi 2001; Matsuoka and Yamazaki 2004; Stramondo et al. 2006). It is a different case with the high-resolution SAR data because we can see a decrease of the backscattering for the pixel where the double-bounce is located, but also an increase in the roof part, since rubble can cause an increase of the backscattering as compared to a smooth roof. Furthermore, where the shadow is present in the pre-event image, some changes are expected in the post-event image, depending on the structures shadowed before the collapse.

As it appears from the aforementioned description of the optical and SAR data, the high resolution has drastically changed the semantic of objects as they were known so far. Indeed the lower resolution caused them to appear differently than the metric or submetric spatial resolution, thus the necessity to introduce new characteristic features and a new vocabulary. For this reason the object-oriented approach seems more promising than per pixel, since with submetric resolution image without having a well-defined semantic for identifying classes of interest we can just identify primitive objects, which are different from objects of interest. Indeed only objects of interest match real-world objects, e.g., the building footprints. Primitive objects are usually the necessary intermediate step before objects of interest can be found by a segmentation and classification process, having

as a smallest image object the pixel. Of course an object can be defined in different ways, depending on our scope and at which scale of detail we want to provide the information. An object can be a building or a neighborhood in a city with a particular type of structure and both of them can give us important information in terms of damage mapping. The following are some examples of applied object-oriented methodologies in real scenario, where very high-resolution optical and SAR data have been used for the seismic events that occurred in Bam (Iran) in 2003 and in the city of L'Aquila (Italy) in 2009.

Case Studies

On December 26, 2003, the southeastern region of Iran was hit by a 6.5 moment magnitude (Mw) earthquake whose epicenter was located very close to the city of Bam. The event had a tremendous impact all over the world, due to a heavy loss of lives, injuries, and destruction; the earthquake caused the death of more than 26,000 residents and injured another 30,000. Additionally, the city of Bam was a UNESCO World Heritage Site and as such it plays an important historical role. The Bam earthquake was the worst seismic event in recent Iranian history. The damage was concentrated in a relatively small area around Bam. Ninety percent of the structures in the city of Bam were left more or less heavily damaged or totally collapsed. In particular, the main historical and traditional adobe buildings collapsed. Contemporary houses demonstrated better resistance to earthquake shake, even though many collapsed due to poor construction practices and the presence of weak stories in the buildings (EERI 2004; Chini et al. 2009). As already highlighted this event was the first one to be imaged by an optical sensor with a submetric spatial resolution (60 cm) such as QuickBird, so for this event we have many papers where the damage mapping was treated making use of these new satellite sensors. Within these, three publications have been selected to show the different scales of products that can be provided and the synergy between the optical and

SAR sensors, but not only and also the impact that the very high resolution can have in the lower-resolution products.

In Chini et al. (2008b) pre- and post-earthquake QuickBird panchromatic images have been used to show the capability of this data to map damage at building scale by means of segmentation approach based on the application of mathematical morphology operators (Pesaresi and Benediktsson 2001; Soille 2003). In this article, a classification procedure was applied to the two panchromatic available data, one taken before (September 30, 2003) and one after (January 3, 2004) the seismic event. The buildings' extraction from one single panchromatic image is not an easy task. Many objects in the imaged scene can be confused because they have very close radiance values: cars with some buildings, shadow with some asphalt roads, soil with some kinds of roofs and so on. Due to the lack of multispectral data with a resolution of 60 cm, a contextual analysis is needed to extract geometric information of objects/classes within the images. Morphological profiles from the original panchromatic images taken before and after the earthquake have been carried out in order to classify all the buildings in the scene. The classification was done so as to avoid false alarms in the change detection process caused by shadow or other temporary objects like cars or recovery tents. For this purpose, the open and close morphological operators have been applied and the derived profiles have been used as inputs to an unsupervised classifier in order to extract the entire map of buildings before and after the earthquake. Hence, after the classification process, each single building has been recognized and then labeled. Finally, the damage estimation can be computed, by comparing the pixel belonging to the same building before and after the seismic event. The percentage of the damaged pixels with respect to the total for each building is an estimation of the damage level (ratio between the number of pixels after and before the earthquake forming the single object). The higher the number of damage pixels, the higher damage level of the buildings. The map deals with a classification criteria where each building of Bam city has

been labeled as belonging to one of three possible damage levels: light or no damage, medium and heavy. Two thresholds have been set in order to identify the three classes. The satellite-based damage map has been compared with a map derived from ground survey, provided by Geological Survey of Iran, which reports the map of collapse ratio. This latter concerns the percentage of completely collapsed buildings with respect to the total number of buildings within a city block. It is worth noting that the information about damage from field survey was given at district scale, while the results from object-oriented approach provided information at building scale. Although the different scales of the maps did not allow a direct comparison, a qualitative accuracy evaluation was done counting the percentage of the three classes from remote sensing data in each regional class obtained from ground survey. It is interesting to highlight that the percentage of heavy damaged buildings (from the object-oriented analysis) increased with the increase of ground survey damage degree.

In Chini et al. (2008b) the semiautomatic classification approach aimed to identify completely or partially collapsed buildings based on the optical satellite images vocabulary; it was basically a change detection approach at building scale, which evaluated how much the radiance value for all pixels of each building changed as an effect of the earthquake. A step forward was attempted in the next article we will describe (Bignami et al. 2011) where an analysis was performed on the sensitivity of textural features at object scale with respect to the damage levels according to the European Macroseismic Scale 1998 (EMS98). Textural features were clearly demonstrated to be a method to overcome the lack of spectral resolution for classification purposes. Indeed texture analysis plays an increasingly important role in digital image processing and interpretation, especially for very high-resolution data (Haralick et al. 1973; Haralick 1979; Pacifici et al. 2009). This is mainly due to supplementary information about image properties it can provide. Such information can be fruitfully exploited for change detection applications as well. In Bignami et al. (2011), the analysis was

focused on the sensitivity of some textural features for change detection purposes; in particular it was focused on earthquake damage mapping. This approach was preferred in order to give information strictly related to each building and to mitigate false alarms weighting per-pixel classification error. Instead of the usual textural features extraction by considering the co-occurrence matrix on a moving window, the proposed method was based on the calculation of textural parameters at object scale. Indeed, the co-occurrence matrix is evaluated by taking into account all the pixels belonging to a single object, i.e., the building, and considering a shift of one pixel in the horizontal and vertical directions. In this way for each building a co-occurrence matrix was obtained. The algorithm makes use of the same dataset as Chini et al. (2008b) and also of some outcomes of the algorithm such as the buildings map, where each building/object was singled out. Stemming from this building map, the textural parameters for each specific object is derived, overcoming the dependency from the window size, which makes the analysis test case dependent. Following the formulation of the textural parameters described in Haralick et al. (1973) and Haralick (1979), for each one of the selected building in the two images, pre- and post-earthquake, four different object textural parameters have been calculated, such as contrast, dissimilarity, homogeneity and entropy. In order to investigate the sensitivity of these parameters to damage degree from EMS98 damage scale, some buildings were selected by the ground truth map described in Hisada and Shibaya (2004), where some buildings, located around eight strong motion stations, were surveyed and classified. The EMS98 classifies five damage levels: G1 (negligible to slight), G2 (moderate), G3 (substantial to heavy), G4 (very heavy) and G5 (destruction). The G1 level can also include the non-damage class, because the difference between G1 and no damaged building cannot be appreciated using this kind of satellite data. Once the four object textural parameters have been derived on both pre-seismic and post-seismic data, the difference between post- and

pre-seismic at object scale has been computed in order to analyze their sensitivity to the damage levels for those building labeled by ground survey. A total of 367 buildings were accounted for in the sensitivity analysis. For each object textural feature the mean value within a damage class from the ground survey was evaluated and the difference between post-seismic and pre-seismic features was calculated. These values have been plotted in respect to the five ground survey damage grade. By observing the plots, some evidence of sensitivity with respect to damage levels are observed. A positive trend in the difference of textural features has been obtained for the contrast, the dissimilarity and the entropy, while a negative trend is visible for the homogeneity. The trends reflect the expected behavior of these textural parameters. In fact, as the damage level of an object increases, the numbers of pixels within the object, which appear scattered, increase. From a textural point of view, the homogeneity of the object should decrease, i.e., the more scattered pixels are, the less homogeneous is the object. On the contrary, the contrast, the dissimilarity, and the entropy increase with the increasing number of scattered pixels. A comparison with textural parameter extracted by using a moving window with a fixed size has also been carried out, highlighting that the trends were not as expected. This work showed that to better understand some discrepancies present between satellite information and ground survey damage grade, an object-by-object analysis is needed. It was stated that the damage level assigned to an object should be validated also from the remote sensing point of view because sometimes the damage level cannot be identified from satellite data. A typical false alarm case is the pancake effect which occurs when severe damage affects a building (G3 and G4 levels), or sometimes it collapses (G5 level), but the roof remains almost undamaged, preventing its identification from space images.

The Bam earthquake was also studied in Chini et al. (2009), where the integration between medium resolution SAR data was analyzed, from 20 m resolution C-band sensor onboard of

Envisat satellite mission and very high-resolution optical data, with the aim of producing damage maps at district scale with three different levels of damage. In this article additional parameters, namely, the InSAR complex coherence and the intensity (or backscattering) correlation, have been computed, since couples of pre- and post-seismic interferometric images were available (two images before and one or two after the event). Both parameters can be derived by combining the pre-seismic pair, the post-seismic, and the coseismic (i.e., one pre-seismic and one post-seismic image) ones. Note that these two features contain slightly different information concerning changes in the scene. The complex coherence is primarily influenced by the phase difference between radar returns, which is a distinctive parameter measured by a coherent sensor like SAR. It is particularly related to the spatial arrangement of the scatterers within the pixel and, thus, to their possible displacements. Conversely, the intensity correlation is more related to changes in the magnitude of the radar return. Unfortunately, for this event, SAR interferometric image pairs have very high values of the perpendicular baseline, around 500 m for both pairs and the resulting high spatial decorrelation prevents their employment from detecting damage levels through the InSAR phase coherence, which has almost the same values both in damaged and undamaged areas when the baseline is too large (Zebker and Villasenor 1992). Concerning the use of the backscattering correlation as an indicator of surface changes, the approach is founded on the idea that the correlation coefficient is high when two images are similar, while it becomes low when changes have occurred in the surface target. Thus, in the latter case, a decrease of correlation of coseismic images is expected to be relative to pre-seismic ones and this phenomenon is expected to increase with the increase of damaged buildings on the ground. The difference between the pre- and coseismic intensity correlations has been averaged within areas of homogeneous damage levels provided from a ground survey map, and it is clearly shown how this difference increases

with the increase of damage level (Yonezawa and Takeuchi 2001; Stramondo et al. 2006). In addition to Envisat SAR data, the information extracted from a high-resolution optical QuickBird image has been used, by extracting the building maps before the earthquake carried out with the adoption of object classification approaches. The building map was used as a mask to restrict the SAR intensity correlation change detection only to built-up areas, in order to reduce possible false alarms. Indeed, in Bam City, there were a lot of vegetated areas, which could affect the value of the correlation. The intensity correlation difference showed an increase of the dynamic range of about 25 % with respect to the non-masked data, using the information on buildings from optical data.

On April 6, 2009, a $M_w = 6.3$ earthquake hit a wide portion of the Abruzzi region in Italy, with the epicenter located 4 km southwest of the city of L'Aquila, whereas the highest damages occurred about 8 km to the southeast. In L'Aquila and in the neighboring villages, the earthquake caused the collapse or irreparable damage to over 15,000 buildings, killing 308 people and causing the relocation of over 65,000 (Stramondo et al. 2011). For this event very high-resolution SAR images, acquired in SpotLight mode (1 m per pixel on ground) from the X-band COSMO-SkyMed satellite mission, were available. The very high resolution images from optical sensors such as QuickBird and IKONOS were available as well. It is interesting to see how information has been exploited in the work of Dell'Acqua et al. (2011), for estimating the damage at districts levels from a post-event SAR image and the fusion with optical images for increasing the accuracy. It is commonly acknowledged that due to speckle effects, single-pixel classification of SAR images leads to unsatisfactory results, and this seems to hold true also when damage assessment is concerned. Satisfying results may be achieved if the damage is assessed at a block level, somehow averaging the unreliable results of pixel-wise comparing pre- and post-event images due to speckle noise. In the Dell'Acqua et al. (2011) article, damage was considered at

pixel scale, in optical data and at block scale, in SAR data, separately. Indeed, the pixel-based approach by using optical data provided useful information on the discrimination between damaged or non-damaged areas. Even though no further classification with respect to damage levels can be retrieved, the information derived from optical imagery can be effective where apparently very high-resolution SAR data is least with the proposed method, and it could be probably the reason why fusion of optical and SAR data in this method is promising. Indeed in this work the SAR textures, which were the features used as damage indicator, were somehow correlated to low damage levels (or affected by other factors than damage), whereas optical data were more suitable to distinguish between damage and non-damage classes. Definitely, the SAR texture was more effective to distinguish between two different levels of damage, in the regions that were identified as damaged by optical data. Some important issues remained still open; such an example could be finding suitable threshold levels for classification in future cases, although significant links between satellite-derived indicators and damage levels have been discovered. It seems that some texture maps computed on SAR data can provide an estimate of damage levels, only if independent information concerning presence or absence of damage in a given block would be available. It is evident from the results that further studies are required and they should be aimed at finding sufficiently independent statistics, extracted from SAR data, which may possibly be linked to presence or absence of damage.

Summary

This entry highlights the characteristics of very high-resolution optical and SAR images that are pertinent for earthquake damage mapping purposes. Automatic or semiautomatic classification algorithms, which make use of this kind of data, have been described as well. Particular attention has been paid to object-based classification approaches, which are more suitable to deal with metric or submetric resolution data.

Relevant case studies, where object-based damage mapping approaches have been considered, are here presented.

Acknowledgment The author would like to thank R. De Meo for reviewing this manuscript.

Introduction

Since impacts of disasters are most felt at the local level, they require proactive action and intervention directly from local authorities and affected communities. However, the extent of impacts varies from one area to another. Highly urbanized areas are typically more vulnerable to natural hazards as a result of environmental and socioeconomic stresses brought about by rapid and often unplanned urbanization. Because of the concentration of population, infrastructure, and resources in urban areas, they stand to lose more in the event of actual disaster. Thus, it is becoming increasingly imperative for city government authorities and local actors in urban areas to develop and enhance their capacity to manage disaster risks in order to protect their development.

Cities have largely and chronically been neglected by national governments and international organizations in terms of dealing with risk

and its contributory factors such as poverty and rapid urbanization (Khazai and Bendimerad 2008). Contrary to popular misconception of local authorities in urban areas having the requisite capacity to address risk on their own, most cities, particularly in the developing world, have actually been ineffective in managing their risk, which remains high and is continuously rising. The relative negligence of disaster risk management as a local responsibility is also exacerbated by the fact that many local authorities are already overburdened by their presently mandated responsibilities.

Disaster risk management (DRM) is defined by the United Nations International Strategy for Disaster Reduction (UN-ISDR) as “*the systematic process of using administrative directives, organizations, and operational skills and capacities to implement strategies, policies and improved coping capacities in order to lessen the adverse impacts of hazards and the possibility of disaster*” (UN-ISDR 2009). Current approaches to managing disaster risk are often characterized by (a) the prevalence of a response or humanitarian perspective rather than a development perspective, (b) the lack of cross-disciplinary and cross-sectoral processes demanded by a more integrated mainstreaming approach that captures the parameters of risk that are relevant to each sector, and (c) the absence of policymaking processes based on consensus building and effective engagement of the concerned stakeholders. These factors are correlated, calling for a holistic approach to urban resilience, one that integrates disaster risk reduction (DRR) with developmental policy and planning, delivery of core services, natural and environmental resource management, and poverty reduction. A methodology that could define needs to be met and why and how to do it is necessary to generate support for allocating resources to disaster risk reduction, especially in view of overwhelming demands from citizens for vital services and to meet day-to-day needs.

The key to manage disaster risks in urban areas without draining the resources of local authorities is to mainstream DRM in the daily functions and services of the city. By integrating

risk reduction parameters in planning processes, such as land use and urban planning, public works, delivery of core services, and emergency response planning, among others, the task of managing disaster risks becomes more attainable. However, mainstreaming DRM in the operations of urban local authorities is easier said than done. Disaster risk management in general is a new field of practice for most city officials and personnel, not to mention that disaster risk reduction implementation itself is complex. It takes time, effort, training, and, most importantly, scientifically designed methods and tools in order to effectively and fully assimilate disaster risk reduction in city functions and ongoing operations. DRM mainstreaming is also closely in line with the commitment of countries to several international conventions and agreements such as the Hyogo Framework for Action for 2005–2015 (HFA) and the UN Millennium Development Goals (MDG), to name a few.

This entry further elaborates the concept of DRM mainstreaming, shows examples of tools that are used for mainstreaming, and provides a case study of an actual application of DRM mainstreaming using the Disaster Risk Management Master Planning (DRMMP) process developed by the Earthquake and Megacities Initiative (EMI).

The Concept of DRM Mainstreaming

Mainstreaming is a core concept of DRM but is seldom understood. Mainstreaming is essential to achieving effectiveness in a DRM structure. It is about defining and distributing roles and responsibilities between national and local authorities and civil society in a way that would result in greater outcome for lower amount of resources. It is about determining the parameters of risk that are most relevant to each sector and function of government and making these parameters an integral part of the governance and management of urban life. An organization that has accomplished mainstreaming has effectively integrated the practice of risk management within its governance, its functions, and operations.

Mainstreaming requires a deliberate and well-founded strategy and consistent applications of policies that strive to pinpoint and enforce roles and responsibilities. Inherent in this process is a policy of decentralization of authority and accountability. The current practice shows an overemphasis on centralization at the national level of all DRM functions. The reasons are twofold:

- (a) Lack of decentralization and coordination structures. The DRM practice is an emerging function of government; sublevel government institutional structure and coordination mechanisms have yet to be devised and put in place.
- (b) Lack of capacity of local authorities. The central authorities of the government are reluctant to provide local government with the authority for DRM out of prudence.

Despite these limitations, a distribution of roles and responsibilities between the various levels of government is critical to achieve mainstreaming. One approach to establish a mainstreaming strategy is to follow the scheme shown in Fig. 1 (EMI 2009). The three encompassing boxes provide a descriptive assignment of roles and responsibilities. Fundamentally, the model represented in the figure indicates that, following other more conventional functions of government, DRM implementation has three principles of mainstreaming: central coordination, local implementation, and participation (Bendimerad and Zayas 2015).

- *Local implementation:* Implementation should as much as possible be delegated to local authorities and local actors. Local authorities cannot mainstream DRM without a clear authority and resources.
- *Central coordination:* The role of the central authorities should focus on establishing policy, enacting regulation, putting in place control processes, allocating resources, and exercising oversight.
- *Participation:* Government (central and local) must open the door to the participation of civil

Building Disaster Resiliency Through Disaster Risk Management Master Planning,

Fig. 1 Framework for mainstreaming disaster risk reduction. Functions are indicative (Source: EMI. State of the practice report on urban disaster: open file report. June 2009)

society, which collectively groups all the active agents of society.

The central government delegates aspects of policy, regulatory powers, and other functions and allocates additional resources to local government. It should in turn monitor the performance of local authorities based on sanctioned guidelines and criteria. The boxes do indicate a strict division between the various entities. In fact, flexibility and coordination are keys to success. Within this mainstreaming framework, an optimization of resources and outcome is accomplished when local authorities are strategically establishing internal policies and process where planning, programming, and action for risk reduction is integral to each of their jurisdictional responsibilities either as a service provider or as a regulator. This process is sometimes referred to as “integrated” or “holistic” approach to DRM.

This framework also suggests that risk reduction can be mainstreamed in local governance by harnessing existing legal mechanisms (e.g., local government acts, environmental management acts, DRM acts and related laws and regulatory mechanisms), processes (e.g., licensing, land use, etc.), and service delivery systems (e.g., health, education, transport, utilities, revenue generation) and making use of such resources. For local authorities, this would translate into having processes and practices that inherently incorporate urban risk reduction in these core functions

that they undertake such as construction and building licensing, land use and urban development planning, environmental management, and social welfare as well as in the services that they provide or regulate. To provide necessary authority, additional reforms are often needed, particularly in aligning DRM laws and policies with other acts that regulate local government functions. The point is that wherever responsibility is located, authority and resources should also be provided.

Review of Tools for DRM Mainstreaming

In line with global efforts to reduce disaster risks by focusing on local-level action through mainstreaming, several disaster risk management models have been developed that integrate disaster risk in local development. A review has been conducted of 76 tools, 10 of which were shortlisted for detailed assessment because of their applicability for local application in urban settings (Berse et al. 2009). “Tools” are used interchangeably with models and instruments and in this context refer to a framework that lays out the methodology for undertaking DRM including the mechanism for implementing the elements in the methodology.

Each tool’s relevance to disaster risk reduction and their applicability or feasibility to the local government’s capacity to institutionalize disaster

risk reduction efforts within its functions and operations were carefully considered and weighed in the assessment. Each tool has its own strengths and weaknesses that local authorities in urban areas can learn from in mainstreaming DRM. Evaluation of DRM tools were based on a set of criteria indicators representing the three principles of mainstreaming, i.e., central coordination, local implementation, and participation. The criteria indicators are meant to assess effectiveness and relevance to DRR processes, feasibility requirements, and applicability to the urban setting especially of developing countries. Through this study (which is not exhaustive), a set DRM instruments have been developed—or at least have the potential—for replication in areas outside of their respective origins and were rated for local adoption in the urban context. A summary of the results of this study is provided here.

Effectiveness

Local Implementation

The paradigm shift in the disaster management policies has elicited the participation and commitment of local governments to a more proactive disaster risk management. It is argued that since local stakeholders are the ones greatly affected in the events of disasters, it is critical for local governments to play a major role in the DRM. This is the very reason for giving emphasis on the local implementation of DRM mainstreaming models.

Of the frameworks reviewed, the following have evolved around the concept of DRM mainstreaming: Comprehensive Hazard and Risk Management (CHARM) Programming Approach (SOPAC 2002), Total Disaster Risk Management (TDRM) (ADRC 2005), Central United States Earthquake Consortium's (CUSEC'S) Disaster Resistant Community (DRC) Model (CUSEC 1997), and the Bangladesh DRR Mainstreaming model (Siddiqui 2007). CUSEC's DRC Model was developed by a consortium that includes both the local community and business sectors and not surprisingly gives the most emphasis on the involvement of

these constituencies in the DRM processes. Although designed to be implemented at the national level, Emergency Management Australia's (EMA) Emergency Risk Management Process (Commonwealth of Australia 2004) can also be developed for local government DRM mainstreaming implementation.

Central Coordination

The reviewed DRM mainstreaming models are consistently aligned with the disaster risk reduction strategies formulated by the DRM authorities of their respective countries. The TDRM as in a few other cases was developed by nongovernmental organizations for application in different cities and countries. The Total Disaster Risk Management implementation strongly encourages endorsement from the central DRM authority and adaptation to the DRM institutional framework of the country of application. The Total Disaster Risk Management developed by the Asian Disaster Reduction Center- Office for the Coordination of Humanitarian Affairs (ADRC-OCHA) was endorsed by the government of Thailand and its central DRM authority and adapted for implementation in the country (ADRC 2005).

Participation

The need for stakeholder participation is a well-established approach used in development work. Its main tenet is that stakeholders are collaborators in a development project at every stage of the process. Through this approach, stakeholders influence and share control over the decisions that affect them and their resources. In essence, the stakeholders drive the development process. They are the ones who decide in the planning, design, implementation, monitoring, and evaluation of the project. In this process, they are guided by experts and specialists who also processed the outcome in a scientifically rigorous output. With this, participation does not only ensure stakeholders' ownership but also encourage commitment. In general, the reviewed models emphasize multistakeholder participation at every stage of the DRM planning process. They also recognize the relevance of the participatory process as

enabling communication mechanisms. Models provide more relevance to particular stakeholders: national authorities (e.g., Comprehensive Hazard and Risk Management and Total Disaster Risk Management), local authorities (e.g., Central United States Earthquake Consortium), business sector (e.g., Central United States Earthquake Consortium's Disaster Resistant Community), or community (e.g., BDRRM, Central United States Earthquake Consortium). At the same time, other tools such as the BDRRM provide specific indications of the targeted stakeholders.

Applicability

Relevance

The reviewed DRM mainstreaming models generally adhere to the main goal of integrating risk management in the development and governance processes in order to reduce risks and mitigate the impact of disasters, albeit employing distinct strategies and aiming at varied focus.

The CUSEC model, for example, prioritizes achieving disaster-resistant communities. With this, the model aims to reduce community vulnerability to natural hazards in order to minimize losses and accelerate recovery (CUSEC 1997). The Emergency Management Australia's Emergency Risk Management Process, on the other hand, focuses on reducing risk by making modifications in the causes of risks (Commonwealth of Australia 2004). Similarly, South Pacific Applied Geoscience Commission Disaster Management Unit's Comprehensive Hazard and Risk Management Programming Approach aspires to develop preparedness and reduce vulnerabilities while increasing resilience of the community (SOPAC 2002). The added value of this particular model is that it engages the implementing institution in hazard and risk management in a more holistic manner as it intrinsically links DRR to national development (South Pacific Applied Geoscience Commission SOPAC 2002). Food and Agricultural Organization's DRM Framework (Baas et al. 2008) follows the same line and aims to reduce underlying factors of risk and to prepare for and initiate an immediate response should

disaster hit (Berse et al. 2009). The Asian Disaster Reduction Center- Office for the Coordination of Humanitarian Affairs' Total Disaster Risk Management model, like the Comprehensive Hazard and Risk Management model, is anchored on risk management. However, the TDRM also focuses on "total" approach of balancing the ability to respond to the consequences of disaster with predisaster actions that lessen the need for response (ADRC 2005).

Feasibility/Resource Requirements

Financial and resource requirement are crucial factors for assessing the implementation potential of a particular DRM mainstreaming model. Oftentimes, the availability of resource dictates the scope of DRM mainstreaming implementation and the strategies or tools that will be utilized. Acknowledging this, most of the shortlisted DRM models signified the use of available resources and the development or enhancement of existing resources whether it be financial/material or human resources. While some DRM mainstreaming models identified low-cost tools and strategies for their implementation, others opted for more sophisticated and high-cost tools or mechanisms.

Apart from relying on the engagement of different stakeholders and the local government for human resources, interestingly Central United States Earthquake Consortium uses the strategy of providing incentives to promote steps and measures to reduce the vulnerability of communities to natural hazards (CUSEC 1997). The Food and Agricultural Organization's DRM Mainstreaming model, South Pacific Applied Geoscience Commission-DMU's Comprehensive Hazard and Risk Management, and the Bangladesh DRM Mainstreaming model all give importance on strengthening the capacities of local stakeholders in disaster management and risk reduction and improving advocacy and awareness (SOPAC 2002). They do not specify what would be the required resources for implementation.

Emergency Management Australia's Emergency Risk Management did more than this by identifying a package of special tools for risk

management (i.e., Unique Identifier System, the Risk Register Database, and the Geographic Information Systems) and at the same time by carrying out emergency risk management training for local stakeholders (Commonwealth of Australia 2004).

Disaster Risk Management Master Plan (DRMMP)

The Disaster Risk Management Master Plan was developed by Earthquake and Megacities Initiative (EMI) to support local-level long-term planning and programming of disaster risk reduction activities. It follows the approach set out in Australian/New Zealand Standard 4360-2004, a standard in risk management developed jointly by Australia and New Zealand and recently adopted by the International Standards Organization as ISO31000 for risk management. The DRMMP is based on EMI's mainstreaming framework that optimizes resources by defining and distributing roles and responsibilities across various stakeholders at all levels of government.

The DRMMP provides opportunity for local authorities to systematically and rigorously identify programs, projects, and activities (PPA) aimed at reducing risk caused by natural and man-made hazards and to define processes for implementing these projects and activities. Local authorities are familiar with the master planning process as it is an integral part of their planning activities in particular for land use planning and transport. These plans constitute the basis for budgeting and investments.

Embedding the three principles of mainstreaming (i.e., local implementation, central coordination, and participation), the DRMMP process is designed to align along core planning processes of local governments and is strategically developed for local government DRM implementation. It is anchored on the regulatory framework that defines mandate and authority of government. It is a methodology for integrating risk parameters into various local government functions. EMI's DRMMP

implementation also strongly encourages formal endorsement from the central DRM authority and adaptation to the DRM institutional framework of the country of application. Finally, the DRMMP process has been designed as an approach for organizing the stakeholders in thematic Focus Groups to ensure efficiency and sustainability using a participatory process with targeted stakeholders.

The DRMMP methodology follows similar principles and processes as other more conventional planning processes, e.g., land use planning, namely,

- It is structured and systematic and follows a consistent step-by-step methodology.
- It is science based and data driven.
- It is multisectoral and multidisciplinary.
- It applies to all hazards.
- It is participatory and consensus driven.

By anchoring on mainstreaming, the DRMMP puts in place a structured approach for setting up a DRM system that is based on science, understood by all, and provides the rationale for investments in DRR programs and projects. As of 2014, the DRMMP has already been applied to eight (8) local authorities, namely, Istanbul (Turkey), Kathmandu (Nepal), Metro Manila (Philippines), Amman (Jordan), Mumbai (India), Pasig City (Philippines), Quezon City (Philippines), and Dhaka (Bangladesh).

Process to Implement the DRMMP

The Disaster Risk Management Master Plan provides a *road map* for a proactive DRM approach, which recognizes that disasters are not just “set-backs” or “roadblocks” to development but result from the paths that development is pursuing. Thus, by changing planning processes, and incorporating disaster risk parameters explicitly in the planning of processes and projects, it can be ensured that in future natural hazards will encounter resilient communities that are capable of withstanding their impact, reduce their losses, cope, and recover normal life faster. Ultimately,

Building Disaster Resiliency Through Disaster Risk Management Master Planning, Fig. 2 The DRMMP workflow (Source: Urban Resilience Master Planning: A Guidebook for Practitioners and Policy Makers, March 2015)

impacts of hazards become mere emergencies rather than disasters.

The undertaking of a DRMMP follows a series of analyses along each of four phases, namely,

- Phase 1: Organization and Preparation
- Phase 2: Diagnosis and Analysis
- Phase 3: Plan Development
- Phase 4: Plan Implementation, Monitoring, and Evaluation
- Legal and Institutional Arrangements (LIA)
- Land Use Planning (LUP) and development controls
- DRM Database and Geographic Information System (GIS)
- Hazard, Vulnerability, and Risk Assessments (HVRA)
- Emergency Management (EM)

Figure 2 provides the workflow process for developing the DRMMP, which can be completed in 12–24 months, depending on the elements that need to be covered. First, the elements that need to be included in the master planning process have to be identified. Some components are core to the DRMMP methodology because they provide the essential scientific information on the DRM practice. These include

Further elements/sectors (e.g., housing, transport, sanitation, health, education, social services, and others) can be added depending on the jurisdictional responsibility of the city. This also depends on what is most relevant to local authorities in terms of priority, access to data, and availability of resources and expertise. For example, in the application of the DRMMP in Greater Mumbai Project, there were additional elements that were included such as Water, Wastewater

and Storm Drainage Systems, and Transportation. This is due to the fact that the Municipal Corporation of Greater Mumbai regulates the delivery of these services. It is important to note that not all sectoral elements fall under the authority of the city or of other agencies of the government. Many could be provided by the private sector or utility companies (e.g., water, power). Others would be a mix of public and private entities (e.g., transport). Other elements may also have to be addressed because of the local context and conditions particular to a city. For example, in the Mumbai application, elements such as Slums, Shelter, and Housing, were likewise addressed because of the unique characteristics of the city that has more than 60 % of its population living in the slum areas.

A listing of additional elements included in the DRMMP includes

- Shelter and Housing (including slums and informal settlements) (S&H)
- Health
- Education
- Construction Codes and Standards (CCS)
- Water Systems
- Waste Water and Storm Drainage Systems (WWSD)
- Power Systems (PS)
- Transportation Systems (TS)
- Solid Waste Management (SWM)
- Telecommunications
- Possibly other relevant sectors

There are other elements that support the whole planning process and are crosscutting in nature. These include

- Training and Capacity Building (TCB)
- Information Education and Communication (IEC)

Training and Capacity Building and Information Education and Communication components facilitate the meaningful participation of stakeholders since their aim is to bring the gap in understanding of DRM concepts and principles between the EMI experts and practitioners and

the stakeholders. Throughout the DRMMP process, the stakeholders are made to understand and take ownership of the types of risks that their city faces as they acquire the competency and tools to be able to manage those risks on their own.

Participatory Approach to Develop the DRMMP

The DRMMP allows for the meaningful participation of stakeholders. By design, the DRMMP provides stakeholders with an opportunity for learning the concepts of hazard, vulnerability, and risk and to understand their relevance to planning. It develops consensus among them on the trade-offs and the rationales for investment in urban resilience. With their engagement in the development of the plan, the stakeholders not only provide essential knowledge to the plan but acknowledge their roles and responsibilities in the implementation of the plan, thus taking ownership. The underlying principle to EMI's participatory approach is that urban DRR can only be made meaningful if stakeholders understand their risks. They should be well informed in order to meaningfully contribute. In most cases, there is a gap in how risk is understood and interpreted by various stakeholders with diverse backgrounds and oftentimes competing interests. Once there is shared understanding of risk, stakeholders can contribute to the work at hand in terms of data collection and validating findings and interpretations of risk assessments that are fundamental to any risk reduction program.

EMI's version of participatory approach was first applied in 2008 in the *Makati Urban Redevelopment Planning Project: Mainstreaming Disaster Risk Reduction in Megacities, A Pilot Application in Metro Manila and Kathmandu*. It was then further tested and applied in various cities and has become EMI's cornerstone strategy to stakeholder engagement in urban DRR. Using this approach, the participation by stakeholders is organized along key sectors that allow for generating inputs across a broad range of stakeholders with different agenda and interests but at the same time facilitate decision and action.

Building Disaster Resiliency Through Disaster Risk Management Master Planning, Fig. 3 Project organization structure of the disaster risk reduction in Greater Mumbai project which shows an example of a flat non-hierarchical structure that is composed of stakeholders from different sectors that are working together in a participatory approach

Typically, implementing the DRMMP requires organizing the stakeholders along the following:

- Creation of a **Project Management Team** (PMT) composed of the project managers and technical experts and specialists who make up the main workforce that will develop the DRMMP. It is multidisciplinary and structured as a single unit incorporating EMI’s experts and counterpart from the host local authority.
- Creation of the **Advisory Committee** which is composed of policy-/decision-making officials who are endorsed as representatives to the project by their respective institutions. It provides the platform to receive input and guidance from the stakeholders and share the project issues, findings, and accomplishments that the members can take back to their respective institutions.
- Creation of the **Scientific Consortium** which is composed of local experts in relevant fields

- addressed by the project. The members of the Scientific Consortium are selected on the basis of their credentials. They advise on the validity of the scientific data and approach and help reach scientific consensus.
- Creation of the **Focus Groups** which are composed of local practitioners, researchers, and community leaders. These include midlevel managers and specialists from the various departments and offices of the city. They are organized along each of the sectors that are being analyzed in the DRMMP. Through the Focus Groups, relevant stakeholders get engaged in the development of the project by providing inputs and tackling issues, as well as validating the assumptions, findings, and recommendations relevant to the project.

Figure 3 below shows an example of the project organization structure of the DRMMP that was put in place in Mumbai. It reveals a flat nonhierarchical structure that puts emphasis on

teamwork and consensus building but at the same time assigns responsibility and accountability to the project team. It requires experts, practitioners, policymakers, community leaders, and private sector working together to provide inputs to develop the elements of the DRMMP. In the Disaster Risk Reduction in Greater Mumbai Project, there were more than 100 members of the Advisory Committee representing various organizations of government, civil society, technical agencies, and the private sector. In the Building a Disaster Resilient Quezon City Project, the various Focus Groups were organized under a Technical Working Group (TWG). They are composed of technical specialists from the different departments of the Quezon City Government officially assigned by the Office of the Mayor to work with EMI to develop the various elements of the DRMMP.

Strong Emphasis on Data and Science

The development of the DRMMP requires a strong emphasis on data and science. It includes collecting evidence to understand the DRM context and situation, assessing the inherent risks of the city, developing an information database on disaster risk management, and identifying the gaps and needs. The following sections describe several key activities that are conducted to produce the required assessments to develop the DRMMP.

Development of the DRM Database and City Risk Profile

A significant part of the effort goes into data collection, review, and structuring all data into a single DRM database. Data must be collected from several city departments as well as from relevant government agencies and other service providers. This is the most challenging task in the process as not all departments willingly share data. The data is typically organized at the resolution of the lowest geopolitical boundary of the city. This will enable an effective use and management of the data by the local and sublocal authorities. A list of the data that needs to be

Building Disaster Resiliency Through Disaster Risk Management Master Planning, Table 1 Data typically collected in the development of the DRMMP

Administrative and institutional	Build environment, including:
Demographic and socio economic	Buildings
Physical profiles including:	Critical and essential facilities
Topology; geology; hydrology; soil, climate	Infrastructure: transport, water, drainage, sanitation, power, communication, health
Land use	High loss facilities

collected is indicated in Table 1 below. The data is compiled in a City Risk Profile shared and validated with all the stakeholders. Knowledge-sharing mechanism is defined and endorsed to ensure the data is kept current and is benefiting other planning functions of the city. In addition to facilitating DRM planning, tax mapping provides another motivation for cities to have a centralized database in uniform format.

Analysis of the Legal and Institutional Arrangements for DRM

The DRMMP process is anchored on the legal and institutional arrangements that define the geopolitical boundaries of the concerned planning authority (i.e., the local government), its jurisdictional responsibility, and the potential elements of the plan. An in-depth analysis of the legal and institutional context is essential in providing legitimacy and credibility to the plan and in avoiding potential jurisdictional conflicts. Several outputs are generated such as a network analysis that shows the organizational chart of the DRM undertaking in the city with key agencies and their relationships. A functional mapping is also completed to indicate functions, roles, and responsibilities of each organization in the DRM process. The results are shared and validated with the stakeholders through focus group exercises to ensure that the DRM organization is understood by all concerned agencies and officials. An example of network analysis is shown in Fig. 4.

Hazard, Vulnerability, and Risk Assessment (HVRA)

The DRMMP is informed by the hazard, vulnerability, and risk parameters which provide the scientific basis for the plan and ensures that the plan is responding to the objectives of risk reduction and resilience enhancement. The parameters defining the current practice of the elements of the plan (i.e., sectors) are checked against the risk parameters to define the gaps and the strategies for improving urban resilience. The hazard, vulnerability, and risk parameters are developed using scientific methodologies (e.g., scenario analysis or probabilistic risk assessment) that provide information on the distribution of damage and the social, economic, and material losses to the city considering both physical vulnerability and socioeconomic vulnerabilities. The risk assessment should be done at the highest resolution possible to provide an accurate and reliable understanding of the risks. The results are presented, discussed, and validated by the stakeholders. The greater the understanding of the risks, the more relevance is given to the master plan.

The Hazard, Vulnerability, and Risk Assessment also provides information on “hotspots” which are areas that have the highest risk for the considered hazards. The scientific approach to defining “hotspots” relies on developing dimensional indicators by which parameters of physical risk (e.g., number of heavily damaged buildings in a certain locality) are combined with parameters that represent the capacity of that particular locality to sustain and recover from the impact of an event (Nardo et al. 2005). Through the hotspots, local authorities will know where they should prioritize the DRR projects. Maps are produced to provide illustrations where the potential problems are highest. They indicate priorities for planning in terms of where the investments should be for reducing risk and building resilience that address area-specific issues. An example of hazard mapping and hotspot analysis is provided in Fig. 5.

Situational Analyses of Urban Resilience Elements

Situational analyses on key urban resilience elements are conducted to provide the baseline for understanding the state-of-the-practice urban DRR. With the support of the experts, the stakeholders are guided through workshop-type exercises where they can determine the gaps relative to standards for urban resilience. Essentially, the stakeholders are presented with the risk parameters which are contrasted with their current practices. In small group exercises, they look at how the current systems and practices for particular development sectors are responding to the risk parameters and the requirements for disaster risk management. In the *Building a Disaster Resilient Quezon City Project*, the development sectors that were considered include population, economic activity, social services, emergency management, institutional and land use administration, and physical resources (EMI and QCG 2014). Figure 6 provides an example of framework for analyzing the resilience of lifeline systems in Greater Mumbai. It provides the work that needs to be done in the assessment process starting from the mapping of the exposure (i.e., the asset at risk) into a geographic information system (GIS), then superimposing the hazard information, then understanding the impact both in terms of direct damage and secondary damages, then assessing the impact on the system serviceability taking into consideration measures of resilience of the system including physical resilience and community resilience.

Putting the Elements of the Plan Together

For each of the development sectors, programs, projects, and activities are identified as concrete actions to reduce risks and improve resilience. Stakeholders undertake the consequential analysis together with the experts. The consequential analysis is an interactive exercise which builds on the situational analysis but looking at “what-if” scenarios aimed at developing options to improve

Building Disaster Resiliency Through Disaster Risk Management Master Planning, Fig. 5 Earthquake risk profile for Quezon City, Philippines, showing the hotspot counties. The map and corresponding information

was generated through the conduct of a hazard, vulnerability and risk assessment, which is a vital component of the DRMMP

Building Disaster Resiliency Through Disaster Risk Management Master Planning, Fig. 6 The diagram, as an example of a situational analysis exercise, shows the lifeline system and resiliencies and how they influence community resilience. The elements of resiliency are numbered from ① to ⑦, each with visual representations. The arrows identify prerequisite elements; for example in

order to assess the geospatial systemic impacts ③ from an earthquake, one must first understand the geographic distribution of the system ① being analyzed and the geographic distribution of the hazard ②, in this case earthquake ground motions and permanent ground deformation. Taken from the *Disaster Risk Reduction in Greater Mumbai Project*. 2011

Building Disaster Resiliency Through Disaster Risk Management Master Planning, Table 2 Results of consequential analysis of a magnitude 7.2 earthquake to physical resources of Quezon City

Primary hazards faulting, shaking, liquefaction, landsliding	Primary damage: building/ structural non-structural/ equipment	Primary loss: life/ injury, repair costs, function, communication/ control	Secondary hazard/ damage: liquefaction. landsliding fire, hazmat, flooding. . .	Secondary loss: business/operations interruptions, market share, reputation
Collapse of water sam Extreme flood Loss of lives, physical injuries Damages to main roads, infrastructure	Damage to water reservoir	Trauma (Stampede)	Possible trash slide in dumpsites	Loss of jobs
	Building collapse (Eastwood, Libis area)	Isolation of victims due to no road/ highways access	Loss of property, lives	Loss of income
	Loss of water supply	Operation interruptions in hospitals	Physical injuries	Loss of opportunities
	Loss of lives		Fire	Eastwood, malls
	Trapped inside the building		Houses made from light materials	Loss of livelihood
	Damage to equipment		Biogas plant explosion	Production halts
	Stranded people		Informal settlers	Businesses, offices
	Chaos/stampede (inside buildings)		Food shortage	No classes
	Contamination of waterways			

the current practice. Through the consequential analysis, the stakeholders achieve an understanding of the impacts of the current practices and define strategies and rationales for reducing these impacts. They also identify the “entry points” for mainstreaming DRR in each particular development sector. Table 2 shows an example of the result of a consequential analysis for a magnitude 7.2 to the Physical Resources Sector of Quezon City.

Next is the establishment of a vision for resilience and a mission to reduce risk through a visioning exercise. In the Disaster Risk Reduction and Management Plan (DRRMP) process in Quezon City, the stakeholders took some time to establish consensus around developing the vision for the city. There was a long gridlock in identifying a common descriptor for the natural environment around descriptors such as habitable, sustainable, resilient, “clean and green.” This is followed by the development of resilience strategies through the conduct of Strengths-Weaknesses-Opportunities-Challenges (SWOC) exercise to formulate and prioritize strategies by

taking into account key internal and external elements that may affect the attainment of the resilience vision and mission.

After reaching consensus on the resilience strategies, programs, projects, and activities are then formulated. Apart from listing down and discussing potential investments, stakeholders also prioritize projects and activities. This **prioritization process** is based on a set of criteria that helps stakeholders focus their attention to interventions that will have the greatest impact in terms of reducing their risk while taking into account their inherent limitations such as budget capacity or resource constraints. The final form of the DRMMP is then validated. An example of a DRMMP program and its related projects are shown in Table 3.

Ensuring Implementation of the DRMMP

The time frame for a DRMMP can span anywhere from 6 to 15 years, depending on the planning cycles of cities. For the DRMMP to be fully

Building Disaster Resiliency Through Disaster Risk Management Master Planning, Table 3 Example of DRMMP program, related projects, and priority ranking of each project

Program 2: Mainstreaming DRR in land use planning and land use management	
Mitigation and prevention projects	Priority
Formulating a communications plan to institutionalize HVRA within Quezon City (with focus on hotspot areas)	Immediate
Mainstreaming DRR in the 2010–2030 comprehensive land use plan	Medium-term
Consultation workshops for pilot project identification and feasibility of selected land use management methods for flood and earthquake risk reduction	Short-term
Program for improving Quezon City Government’s capacity and expertise in building and infrastructure construction project development permitting, monitoring and evaluation	Medium-term
Restructuring existing M and E program for stakeholder response(s) to and development impacts of Quezon City Government’s projects on disaster risk reduction and management	Short-term
Pilot projects on preferred land use management methods (e.g., development regulations, zoning earthquake hazard areas, floodway zoning and set-backs, fire zones)	Short-term

B

implementable, there has to be a clear understanding of the legal and administrative processes of a city that concerns with approval of mandated plans. This requires knowing who approves, when, and through which step in the approval process should the DRMMP be incorporated so that it becomes integrated in the budgeting cycle. This way, it is ensured that budget for priority projects identified in the DRMMP gets allocated in the overall budget of the city. Figure 7 below provides an example of the budget approval process of Quezon City indicating how the Local Disaster Risk Reduction and Management Plan (LDRRMP) gets integrated in the Annual Investment Plan (AIP). The Annual Investment Plan refers to the indicative yearly expenditure requirements of cities that will be integrated into their annual budget.

Understanding who approves, when, and through which steps in the approval process of cities helps ensure that DRMMP projects and activities are incorporated in the budget and, as such, get funded.

Monitoring, Evaluation, and Communication

To track the progress (or lack of progress) of implementation, monitoring and evaluation tools are developed. One of these tools is to develop a set of Indicators that set initial

benchmarks and can be used to measure progress. The first is the quantitatively derived **Urban Disaster Risk Indicators** (UDRI) which provide a holistic view of disaster risk in a local authority by capturing the direct physical damages and the aggravating social conditions contributing to total risk. The model and methodology referred to here as the Urban Disaster Risk Indicators was originally developed for the Inter-American Development Bank through the IDB-IDEA Indicators Program by the Institute of Environmental Studies (IDEA) of the National University of Colombia, Manizales (NUCM) (Cardona 2003; Carreno et al. 2006). In the context of EMI’s DRMMP methodology and approach, the indicators were used as an innovative risk communication tool to engage stakeholders in understanding their involvement and taking ownership of the risk factors in the city. Besides the initial EMI implementation in Metro Manila (Fernandez et al. 2006), the risk indicators have also been successfully implemented with stakeholders in Istanbul (Khazai et al. 2009), Amman (Bendimerad et al. 2009), Mumbai (EMI and Municipal Corporation of Greater Mumbai 2011a), and Quezon City (Bendimeard et al. 2013). The application of the Urban Disaster Risk Indicators in a city will prove its value if it is “mainstreamed” within the DRM practices and other planning processes that impact DRM in the city. To reach this objective, the indicators have been linked to the quantitative outputs and

Building Disaster Resiliency Through Disaster Risk Management Master Planning, Fig. 7 Example of a budget approval process in Quezon City, Philippines

highlighting how the local disaster risk reduction and management plan gets integrated into the annual investment plan

analyses of the DRMMP. Guided by recommendations following implementation of the risk indicators by EMI in different cities, the current methodology encompasses the following three broad areas:

- To develop the system of indicators in close collaboration with the technical staff and officials in a city, to engage them in the development of the data and the understanding of the conceptual framework and methodology, and to ensure ownership over the indicator system and its periodic updating and upgrading
- To work closely with the Focus Group, in evaluating the indicators, such that they are relevant to the megacity scale of analysis, represent the conditions and reality of socio-economic vulnerability in the city, and reflect the outcomes of the various studies undertaken as part of the DRMMP (e.g., earthquake risk assessment, transportation study, housing and shelter, land use planning, construction codes and standards, water supply and water treatment analysis, etc.)
- To implement the system of indicators through a process of engaging a wider group

of stakeholders in the city, such that they are used as an effective risk communication tool that inherently relates to the city-level DRM practices; as a planning tool that aids in correcting, reviewing, and deciding on where to invest resources; and as Disaster Risk Management benchmarks which assist in policy decision-making and monitoring of different risk reduction practices implemented at the local level.

The second group of indicators is the qualitative **Disaster Risk and Resiliency Indicators** (DRRI) that is a set of ten (10) indicators that establishes initial benchmarks to measure to what extent risk reduction approaches have been mainstreamed in the organizational, functional, operational, and development systems and processes of local governments (EMI and MCGM 2011b). The Disaster Risk and Resiliency Indicators are linked to the priorities of the *Hyogo Framework for Action 2015–2015*. The aim of these indicators is to understand how well the local authority is performing in mainstreaming DRR into different sectors based on predefined benchmarks and performance

Building Disaster Resiliency Through Disaster Risk Management Master Planning, Fig. 8 Disaster risk and resiliency indicators (DRRI) (Source: EMI and MCGM (2011b))

targets. The rationale for selecting the 10 DRRRI indicators can be traced in Fig. 8 by following the information from top to bottom of the chart. The main aim of the DRRRI indicators is to track progress on the **mainstreaming** of risk reduction approaches in the city's organizational, functional, operational, and development systems and processes. The mainstreaming goal is further divided into three **strategic goals** shown in the chart. Each of the strategic goals corresponds to one or more **key areas** analyzed in the DRMMP where these goals are to be implemented. Finally, two indicators corresponding to each of the five key areas of mainstreaming are shown. Mainstreaming risk reduction and achieving risk resiliency cuts across all the key areas and all the 10 indicators shown below. Thus, the stakeholders using and scoring the indicators should look at *all 10 indicators* together from the

perspective of their institutions and not only the indicators that relate most closely to their activities.

The scores for the DRRI are derived from a self-assessment along key functional activities/policies undertaken by the DRMMP Focus Groups. A handbook is developed to describe the organization of the indicators, a rationale for their selection, and provide guidelines for their implementation and scoring that is contextualized to the city for which it is implemented by providing "guiding questions" and "evidence for discussion" derived from in-depth interviews with stakeholders along each indicator (EMI and MCGM 2011b). With five Performance Target Levels of attainment: little or no awareness, awareness of needs, engagement and commitment, policy engagement and solution development, and full integration, the DRRI allocates a

ranking for the 10 indicators that fall under the main 5 areas of mainstreaming, resulting in a graphic visualization of the mainstreaming disaster risk reduction at the Municipality at a point in time.

The Indicator System is also used as a risk communication and planning tool to assist in policy development, decision-making, and in monitoring the effectiveness of programs, projects, and activities. In actual practice, however, there is no clear motivation for cities to monitor performance and outcome of DRR investments beyond accounting for the number of projects and activities conducted. This is also because there are no existing tools as yet for monitoring and evaluating performance of DRR programs, projects, and activities that have been developed for cities.

Lessons Learned

Building resilience, especially within the context of urban areas, requires not just raising awareness on risk reduction but actual investments on programs, projects, and activities that reduce risk. For the plan to be fully understood, accepted, and supported, it has to engage a broad range of stakeholders at all stages of the planning process. However, they have to be equipped with the knowledge and tools to be able to participate meaningfully and contribute to resilience building. Stakeholders have to understand what types of risk they face, what are the implications of these risks to their own mandated responsibilities, what options are available to them to reduce their risk, and what possible trade-offs they need to make in order to prioritize limited resources and address inherent constraints.

Full implementation of the DRMMP, however, requires continued technical assistance. Even if funding is available from cities to implement DRR projects, oftentimes, they lack the resources to manage and undertake DRR projects. It is a resource-intensive approach. The DRMMP only provides the roadmap for change in practice from a reactive to a more proactive approach. For the actual change to take place, the

city has to make continued investments in the medium to long term to make sure that it continues on the path toward risk reduction.

Summary

Local authorities have difficulty in dealing with the risks from disasters due to the fact that they are overburdened by their development aspirations and mandated responsibilities. Mainstreaming DRM in the daily functions and services of the city is the key to manage disaster risks in urban areas without exacerbating cost for local authorities. By incorporating disaster risk parameters explicitly in the planning of processes and projects, it can be ensured that in future, natural hazards will encounter resilient cities that are capable of withstanding their impact, reduce their losses, cope, and recover faster. Ultimately, impacts of hazards become mere emergencies rather than disasters.

Mainstreaming necessitates the distribution of roles and responsibilities between the various levels of government and with the society. It gives emphasis to the local authority's implementation role, central government's coordination function (manifested in the control processes, allocation of resources, and exercising oversight on the performance of the local authority), and the participation of the civil society which is crucial in all facets of the process. Thus, it optimizes resources from these stakeholder institutions to reduce the risks.

Following the mainstreaming tenet, the DRMMP provides a road map for a proactive DRM approach to support local-level long-term planning and programming of disaster risk reduction activities. It follows a series of analyses in four phases, namely, (1) Organization and Preparation, (2) Diagnosis and Analysis, (3) Plan Development and Plan Implementation, (4) Monitoring and Evaluation. The DRMMP process is designed to align along core planning processes of local authorities. Furthermore, it provides stakeholders with an opportunity for learning the concepts of hazard, vulnerability, and risk and to understand their relevance to planning.

The DRMMP was developed taking into consideration other related DRM models that focus on local-level action through mainstreaming.

With DRMMP's strong emphasis on data and science, evidences are collected to understand the DRM context and situation, assessing the inherent risks of the city, developing information database on DRM, and identifying the gaps and needs. These tasks are achievable through a participatory approach involving a broad range of stakeholders. Implementing the DRMMP requires organizing these stakeholders into (1) Advisory Committee, (2) Scientific Consortium, and (3) Focus Groups. Guiding these groups is the Project Management Team.

The DRMMP provides opportunity for these stakeholders to understand the parameters of vulnerability and risk in the context of their own responsibilities and functions. With this knowledge, they can systematically and rigorously identify and prioritize programs, projects, and activities to implement in managing and eventually reducing their risk. These projects and activities are institutionalized by integrating these in the budgeting cycle. This way, it is ensured that budget for priority projects identified in the DRMMP gets allocated in the overall budget of the city. Monitoring and evaluation tools are then developed to track the progress (or lack of progress) of implementation.

With their engagement in the development of the plan, the stakeholders not only provide essential knowledge to the plan but acknowledge their roles and responsibilities in the implementation of the plan, thus taking ownership. By anchoring on mainstreaming, the DRMMP puts in place a structured approach for setting up a DRM system that is based on science, understood by all, and provides the rationale for investments in DRR programs and projects.

Building Monitoring Using a Ground-Based Radar

Guido Luzi and Michele Crosetto
CTTC Division of Geomatics, Av. C.F. Gauss,
Castelldefels, Spain

Synonyms

Displacements; Measurement; Natural frequencies; Real aperture radar; Structural health monitoring

Introduction

This entry is focused on a terrestrial remote sensing technique that can provide a valuable input to earthquake engineering: the real aperture radar interferometry. In the last decades non-contacting measurement techniques based on optical sensors that can be employed for vibration monitoring have been largely described in the literature (Passia et al. 2008; Nassif et al. 2005; Gueguen et al. 2010). As an example, techniques like the Scanning Laser Doppler Vibrometry (SLDV) appear to be an appropriate non-contacting alternative to accelerometers, offering wide frequency bandwidths (0–200 kHz for the most common models) and extreme sensitivity to velocity and displacement (down to 2 pm). On the other hand, they suffer important limitations, due to constraints in the maximum observation angle and the maximum working range. In addition, they might need external acoustic stimulation to carry out measurements with adequate sensitivity, as described

in Esposito et al. (2004). Finally, they measure velocity, not displacements. Although less frequently, the use of microwave sensors to evaluate the vibration state of structures as buildings, bridges, and wind turbine towers has been investigated (Tarchi et al. 1997; Farrar et al. 1999; Pieraccini et al. 2003; Pieraccini et al. 2006; Bartoli et al. 2008; Pieraccini et al. 2008; Luzi et al. 2012a). Microwave techniques measure directly the displacement and have demonstrated to be an effective tool when the monitored displacements are down to tens of microns. Its capability to provide input data that can be used in a modal testing has been assessed, and the obtained results finally encouraged the production of radar instrumentation aimed at this application (Coppi et al. 2010). A coherent Real-Aperture Radar (RAR) is able to measure and monitor the natural vibrations of buildings, structures, and infrastructures. The main observations provided by the sensor are the displacements between the radar sensor and the observed target. The displacements can be observed at relatively high frequencies, up to 100 or 200 Hz with currently available sensors, thus providing a dense sampling of the displacements over time and space. For this reason, the technique is able to measure and monitor the vibrations of the observed objects. It is possible to derive key information of the observed objects as the main vibration frequencies, the main vibration modes, etc. from the displacement time series. There are two main potential applications of the described technique. The first and more consolidated is structural health monitoring, where RAR can provide input for the characterization of engineering structures, especially of their structural systems. This input can be provided periodically to determine the current state of system health and, in particular, to monitor its aging and degradation. In addition, the RAR can provide a valuable input after extreme events, such as earthquakes or blast loading, for rapid condition screening and assessment of the integrity of the structures at hand. The second potential application is the seismic risk evaluation of populated and industrialized areas that are seismically

active. This can be achieved through the measurement of dynamic parameters of buildings and structures, which can be done using a RAR system, and the dynamic parameters of the underlying soil in order to assess possible resonance phenomena.

This entry is organized in four main sections. The first one explains the RAR working principle and the main characteristics of the RAR measurements. The second to fourth sections describe three examples of vibration measurement: a tall tower, a building, and a bridge.

Working Principle

Radar is a well-known instrument able to detect and range objects. It sends a modulated electromagnetic signal, the transmitted pulse, along the line of sight (LOS), and receives the portion of the signal reflected by the illuminated area. Different objects or parts of the illuminated area will reflect the microwave radiation with different intensities: the basic signal provided by a radar is a profile of the intensity backscattered from the scene as a function of the distance, usually referred as “range profile.” The radar acquires simultaneously the contributions from the different parts of the structure included in its antenna field of view (FOV), and different amplitude peaks correspond to contributions from parts of the observed structure located at different distances. The FOV of the radar is dictated by the pulse width and the antenna characteristics. The elementary sampling volume of a radar measurement is usually called radar bin and different bins are used to isolate different parts of the monitored structure. Such vision of the radar prevents to see details as optical systems do, but at the same time, this averaging allows to enhance the general behavior of the structure. In addition, the radar acquires all the bins simultaneously (with respect to the observed phenomenon) thus allowing to achieve a spatial sampling useful to estimate modal shapes. Reflecting properties of a given structure are strongly related to its geometry and the dielectric characteristics of the medium: for

example, metal objects, corners, and plane surface perpendicularly oriented with respect to the radar LOS display high values of reflectivity. If the reduction of the signal strength during propagation is not dramatic, that is to say in radar nomenclature if a good signal-to-noise ratio (SNR) is preserved, the received radar signal permits to retrieve the distance of the objects. The starting point is to achieve a good acquisition, consisting in selecting an observation geometry providing a valuable range profile, i.e., a signal where the bins of interest show a strong response. The RAR is only sensible to displacements along the LOS. For this reason, another important point is the selection of geometry where the LOS and the displacement are as much parallel as possible.

The minimum displacement detectable for conventional radar is dictated by the range resolution, i.e., the capability to distinguish different targets along the LOS, and this is usually not better than some tens of centimeters. Conventional techniques based on amplitude processing are not sufficient to measure the vibration displacements expected from building, which can reach values down to a few microns. On the other hand, interferometric techniques can be exploited to evaluate range variation along the LOS. Interferometric processing can be used only when the radar is coherent, i.e., able to measure not only the amplitude but also the phase of the received echoes. In this way, distance variations of the order of small fractions of the transmitted wavelength, which occurred between two or more acquisitions, can be estimated by comparing the phase of signals acquired at different times. A radar system designed to acquire periodically a set of received echoes, amplitude and phase values, of an entire range profile can provide a phase variation signal of each bin at the corresponding sampling frequency. Now, using the basic formula of differential interferometry, here below drawn as Eq. 1, these phase variations, $\Delta\phi(t)$, can be translated to displacement along the LOS time series, $d_{\text{LOS}}(t)$, for each bin:

$$d_{\text{LOS}}(t) = \frac{\lambda}{4\pi} \cdot \Delta\phi(t) \quad (1)$$

According to Eq. 1, the shorter the wavelength, the higher the sensitivity of the measurement: for a Ku radar, with wavelength $\lambda = 1.76$ cm (operating frequency = 17 GHz), a phase variation of 1° , typically achievable using a state-of-the-art sensor, corresponds to a displacement of ≈ 20 μm .

Equation 1 is a first approximation because it does not take into account some potential sources of error in phase estimation, but it is usually valid in the application here described; for a detailed discussion on this topic, see Luzi et al. (2012b). The standard deviation of the estimated displacements is related to the standard deviation of the measured phase, which in turn depends on the SNR of the radar measurement (Coppi et al. 2010). Vibrations with very small amplitudes, down to ten microns, can be detected when a good range profile with SNR peaks of up to 70 dB is acquired. The SNR must be statistically estimated when secondary undesirable vibrating targets (clutter) are included in the radar bin: its value decreases and the error in phase estimate increases. For this reason, and due to the high variability of the experimental conditions, it is very important to optimize the measuring conditions to acquire a good range profile.

A typical geometry used to monitor buildings is when the radar is positioned close to the base of the building, observing it along a LOS with an angle of inclination α with respect to the horizon. According to the radar equation, the operating distance and the surface characteristics of the backscattering surface strongly affect the radar response. The strength of the received echo must be maximized, case by case, selecting the best observational position. This can be achieved by choosing a distance and an angle of observation able to assure a good range profile and a radar LOS close to the main direction of the observed displacements. Then, the displacement time series can be retrieved from a range profile. The measurement procedure is graphically resumed in Fig. 1 and consists in: (1) collecting an

Building Monitoring Using a Ground-Based Radar,
Fig. 1 Scheme of a standard procedure aimed at retrieving displacement time series from a radar acquisition. The radar collects an amplitude profile as a function of the

range, sampled at regular spatial steps, the radar bins. A displacement time signal is obtained from the interferometric phase of the echo of the selected bin using Eq. 1

amplitude profile as a function of the range, sampled at regular spatial steps (radar bins); (2) obtaining the interferometric phase of the echo of the selected bin; and, finally, (3) transforming the phase temporal variations into displacement time signal for analysis and processing using Eq. 1, as, for example, to calculate the spectral content of the signal.

The acquired data can be processed through conventional signal processing tools. Due to the statistical characteristics of the sampled phenomena, random and stationary, a typical approach consists in calculating the Power Spectral Density (PSD) using the Welch method (Welch 1967).

Nowadays only a few companies market radars for vibration monitoring; as a reference, the main characteristics of one of the interferometric radar most frequently cited in the literature and available at the CTTC, the IBIS-S,

manufactured and marketed by IDS (Ingegneria dei Sistemi SpA), are summarized. It is important to note that the results here discussed do not basically depend on the radar system used. IBIS-S is designed to monitor large structures as bridges and wind turbine towers. The system consists of a sensor module, a control PC, and a power supply unit. The maximum acquisition rate is currently 200 Hz. This parameter depends on the selected maximum range and decreases as the distance increases. The sensor is installed on a tripod equipped with a rotating head used to adjust the bearing of the sensor towards the investigated structure. The radar equipment is a continuous-wave (CW) step-frequency (SF) transceiver, which transmits continuous waves at discrete frequency values, sampling a bandwidth B at a constant interval. The transceiver transmits an electromagnetic signal at a central frequency of 17.2 GHz with a maximum

Building Monitoring Using a Ground-Based Radar, Fig. 2 Photography of the tower and the radar sensor (left) and a simple scheme of the measurement geometry

indicating the fraction of the displacement (*bold arrow*), d_{LOS} , detected by the radar (*right*)

bandwidth of 300 MHz, necessary to perform a range resolution of 0.5 m; details on the functioning principle can be found in Gentile (2011). The location and the dimension of the measured radar bins are dictated by the range resolution and the transmitting and receiving antennas. Antennas with different gain and aperture can be exchangeable; the most frequently used are pyramidal horns whose FOV is about 0.18 rad. At 10 m distance from the target, a 3 m² area is approximately illuminated, and this value increases as the observation angle with respect to the horizontal increases. The sensor unit is managed by a control PC, through a standard USB communication, which is provided with system management software used to configure the acquisition parameters, store the measurement data, and show the displacements in real time. The power supply unit provides about 5 h of autonomy. The equipment is quick and easy to install and can be used both day and night, and in almost any weather conditions.

Vibration Measurement of a Tall Tower

The first example here discussed is the monitoring of a tall tower, the Collserola communications tower, designed by the architect Norman Foster, which serves as a telecommunications tower for Barcelona and its neighborhood. The tower stands from an altitude of 445 m a.s.l., reaching a maximum 266 m height above the ground and 286 m above its base, see Fig. 2. It is made up of five main elements: a concrete shaft, a metal mast, block of platforms, pre-tensed metal guys, and fiber guys. The lower guys are steel cables anchored to concrete blocks; the remaining ones are Kevlar fiber guys. This structure represents an ultimate case from the measurement point of view for different reasons. Firstly, the tower is very high; thus, the magnitude of the amplitude of oscillation of its top, in normal wind conditions, is typically of several millimeters. Secondly, this assures a high number of bins available for data

Building Monitoring Using a Ground-Based Radar,
Fig. 3 Range profile, intensity of the radar echoes as
 a function of the range expressed in bins, obtained from

a tower monitoring. A selection of bins, to be processed
 and analyzed, is marked

interpretation. Finally, its geometry and composing materials, metal and concrete, offer a strong radar reflectivity and this allows acquiring data from ranges up to hundreds of meters. It is worth noting that an analogous monitoring carried out with conventional point-wise sensors, e.g., accelerometers, would be unadvisable due to its high costs and the strong electromagnetic noise of this environment.

Different contributions from parts located at different heights can be clearly identified and selected for processing and observing a range profile acquired at a distance of 266 m from the tower and with an observation angle of 37° (Fig. 3). A typical approach consists in selecting a set of bins sampling the entire height of the structure and drawing the variation of the measured displacement as a function of the time. Figure 4 represents the starting point of the

analysis of the vibration behavior of the monitored structure. The curves retrieved from this plot indicate that the amplitudes of the displacement increase with the height; this trend fits the main mode of vibration of the tower, similar to the first mode expected from a clamped beam. The period of oscillation is also easily calculable in approximately 3.7 s (frequency 0.27 Hz). A spectral analysis has been carried out through the estimation of the PSD calculated using the Welch method (Welch 1967) to look for further vibration modes and deepen the analysis of the vibrating characteristics of the tower. The PSD calculated with the following configuration is plotted in Fig. 5: windowing duration = 50 s, type = Hamming, overlapping between windows: 66 % for different bins. The results obtained indicate the presence not only of the 0.27 Hz peak but also further peaks at 0.49 and

Location of the seismometers (#104 and #107) with respect to the building, and radar bins (#53 and #69) selected from the range profile, to perform a radar data validation

0.72 Hz. Some minor peaks, probably caused by the cables and its interaction with the tower, are also present.

Case studies aimed at estimating vibration characteristics of towers of different shapes and heights, selected among architectural heritages, have been carried out by different authors (Pieraccini et al. 2005; Atzeni et al. 2010; Gentile and Saisi 2011).

Comparison of Radar Observations and Conventional Measurements: The Case of a Building

Radar observations can be integrated with some standard point-wise measurements as a support to model calculation of the modal shapes of the investigated structures. This is the case described in Negulescu et al. (2013), where a building, part of a sportive complex located in Font Romeu (France), was monitored by means of radar and several accelerometers, and the results obtained were compared with a model calculation. The building has a reinforced concrete structure, with double basement, ground floor, 10 storeys, and a total height of 33 m (not including the basement). In this study, several sensors were

placed, in two different configurations, on the roof and at different heights of the structure. The experiment was carried out with the aim of comparing seismometer data with the displacement retrieved from several radar bins. In particular, a direct comparison was carried out between the data obtained using two radar bins and the closest sensors installed in the building, whose position is shown in Fig. 6, where the geometry of the measurement is also depicted. The seismometer acquisition set includes eight sensors and a wireless networking connection was used during the measurements. The normalized PSD calculated for the displacement signal retrieved from the radar measurements and that obtained from microtremor signal are compared in Fig. 7.

The location of the main peaks is almost coincident and the radar signal shows some minor peaks too. The amplitude is a little different; this can be imputed to the fact that the radar only measures the LOS component of the displacement and the two sensors are not exactly positioned in the same point. The agreement between radar observations and seismometer measurements was also confirmed by numerical model calculation and modal shape estimation (Negulescu et al. 2013).

Building Monitoring Using a Ground-Based Radar, Fig. 7 Comparison of the normalized Power Spectral Density (PSD) functions from the records obtained using the radar technique, bin #69 (*top*) and the seismometer #107 (*down*)

Vibration Measurement of a Bridge

Bridge monitoring is an application where the technique has been thoughtfully studied and validated (Gentile 2010). Radar can be used for both static (Pieraccini et al. 2007) and dynamical studies (Stabile et al. 2013). Cable-stayed bridges can especially benefit from radar monitoring, with moderate time and cost recourses with respect to the use of conventional sensors. In this case, the radar monitoring is usually carried out with two different geometries. The first one aims at detecting the main features of the deck vibration, with the radar positioned below the bridge deck acquiring a range profile where the different bins provide a spatial profile of deflection which can occur both due to the wind and the ambient

solicitation as microtremor. The second position is carefully selected to detect the behavior of the stay cables avoiding the direct influence of the deck vibration. In this second case, the main objective is to acquire a range profile where the different stay cables are clearly identified. Figures 8 and 9 show the two geometries used during the monitoring of a cable-stayed bridge in Amposta (Spain), over the Ebro River.

A typical signal acquired during the transit of a vehicle using the geometry depicted in Fig. 8 is shown in Fig. 10. The displacement responses of different bins of the bridge, corresponding to a sampling of half of the bridge deck, are jointly plotted. From Fig. 10 the difference in the deflection for the different bins is noticeable: the central part of the bridge (bin #81) lowers down to 4 mm,

Building Monitoring Using a Ground-Based Radar, Fig. 8 Photography of the radar pointing towards the deck (a); range profile acquired (b); scheme of the

geometry of acquisition indicating the selected bins: bin 25, 47, 66, 81, 106, and 121 belong to the bridge deck, while bin 260 corresponds to the pier (c)

Building Monitoring Using a Ground-Based Radar, Fig. 9 Photos and geometry of the acquisitions with the radar pointing towards the inner stay cables positioned within the two pillars (*left*) and watching the set of guys tied to the soil (*right*)

while the part close to the pier (bin#25) experiences a 500 μm lowering. Using the second geometrical configuration (Fig. 9), the radar observation is focused towards the cables. In this case, the measurement of the natural frequency of the cable can be used to estimate the

tension force of the cable (applying a formula based on the tau string model; see Caetano and Cunha 2011; Gentile and Ubertini 2012; Luzi et al. 2014). The calculation of the PSD of the displacement signal allows detecting the main vibrating frequencies of the cables. Figure 11

Building Monitoring Using a Ground-Based Radar, Fig. 10 Temporal displacement signal for four bins, retrieved from radar measurements carried out according to geometry shown in Fig. 8. Different colors refer to different bins

Building Monitoring Using a Ground-Based Radar, Fig. 11 PSD calculated for two bins corresponding to two stay cables. Different colors refer to different bins

shows the results obtained from the simultaneous measurement of the displacements of two bins corresponding to two cables.

The values of the main peaks displayed in Fig. 11, 3.52, 7.04, 10.58, 14.16, 17.78, and 21.52, show that they are related to each other by a linear relationship. In fact, they are natural multiples of the fundamental frequency, 3.52 Hz, although the higher values gradually deviate. The first frequencies are in agreement with the values

expected from the tau string model, thus allowing the application of the model and the estimation of the tension force of the cables. It is worth noting that obtaining the same information using standard local sensors as accelerometer should be unfeasible. Besides, the knowledge of the spectral behavior of all the stay cables can also be used for evaluating the health state of the structure or comparing these experimental results with model analysis provided by structural engineering analysis.

Summary

In this entry a radar technique applied to the monitoring of vibrations of structures as tower, buildings, and bridges has been introduced. After presenting the working principle and briefly describing a commercial radar system, a measurement procedure underlying the main critical aspects has been summarized. Experimental results from three case studies are then commented. The first is the monitoring of a tall tower which, thanks to the strength of the radar response and the millimeter amplitude of oscillation of its top, allows achieving abundant information. This monitoring also demonstrated that, in the best conditions, the technique is capable of acquiring data at ranges up to hundreds of meters. The second example shows a case where radar data has been validated using a network of standard point-wise measurements (seismometers). The last case study concerns the monitoring of a cable-stayed bridge, an application thoughtfully studied and validated by several authors. In this last case, the technique also allows detecting the vibration characteristics of the cables with moderate time and cost resources.

Buildings and Bridges Equipped with Passive Dampers Under Seismic Actions: Modeling and Analysis

Theodore L. Karavasilis, George S. Kamaris and Angelos S. Tzimas
School of Engineering, University of Warwick, Coventry, UK

Synonyms

Bridges; Numerical simulation; Passive dampers; Steel buildings; Structural design

Introduction

The scope of this contribution is the presentation of numerical models and analysis methods for structures equipped with passive dampers. The principal function of passive dampers and their application in buildings and bridges will be discussed. The most common types of passive dampers and the constitutive models used to simulate their hysteretic behavior will be presented. Finally, the analysis methods for seismic design and assessment of structures with passive dampers are covered.

Passive dampers include a variety of materials and devices that can enhance the damping, stiffness, and strength characteristics of structures. Passive dampers are suitable both for retrofitting existing vulnerable structures and for designing new ones and have been developed for a number of years with a rapid increase in applications in the mid-1990s. Passive dampers can significantly reduce plastic deformation demands on the primary lateral load-resisting system in addition to decreasing velocity and acceleration demands on non-structural components (Soong and Spencer 2002; Symans et al. 2008). Different types of passive dampers have been developed for seismic protection of structures such as viscous fluid dampers, viscoelastic solid dampers, elastomeric dampers, friction dampers, and metallic dampers.

Other devices that could be classified as passive dampers include tuned mass and tuned liquid dampers.

Passive dampers are typically used within conventional lateral load resisting systems to dissipate a significant portion of the seismic input energy (Christopoulos and Filiatrault 2006). The degree to which a passive damper is able to achieve this goal depends on the inherent properties of the lateral load resisting system, the properties of the passive damper and its connecting elements, the characteristics of the ground motion, and the limit state being investigated (Symans et al. 2008). Over the past decades, passive dampers have been specified for application to buildings and bridges with a wide variety of structural configurations. The growth in application of passive dampers has been steady to the extent that there are now numerous applications (Soong and Spencer 2002).

The first design/analysis procedure for buildings with passive dampers was published in SEAONC (Whittaker et al. 1993). The intent of these guidelines was to direct engineers in locating dampers in the lateral load resisting system to reduce repair costs and business interruption due to a severe earthquake. In the mid-1990s, the Federal Emergency Management Agency (FEMA) funded the development of guidelines for the seismic rehabilitation of buildings proposing, among others, basic principles for the seismic design with passive dampers. The outcome of this effort was the *NEHRP Guidelines for the Seismic Rehabilitation of Buildings*, FEMA Reports 273 and 274 (ATC 1997a, b). Later on, the 2003 *NEHRP Recommended Provisions* (BSSC 2004) included a chapter on design and analysis methods for buildings with passive dampers. These methods were reformatted and included in the 2005 edition of the ASCE/SEI 7-05 standard *Minimum Design Loads for Buildings and Other Structures* (ASCE 2005). The 2003 *NEHRP Recommended Provisions* (and the current 2010 ASCE/SEI 7 standard (ASCE 2010)) allow a reduced design base shear force for the seismic design of buildings with passive

damping systems where the expected performance is similar or higher than that of buildings with a conventional lateral load resisting system.

Recent analytical and experimental research showed that steel moment-resisting frames (MRFs) with elastomeric dampers can be designed to be lighter and perform better than conventional steel MRFs under the design basis earthquake (DBE; 475-year return period) (Karavasilis et al. 2011a, 2012a). However, it was shown that it is generally not feasible to design steel MRFs with passive dampers at a practical size to eliminate inelastic deformations in main structural members under the DBE (Karavasilis et al. 2011a). To address this issue, a seismic design strategy for steel MRFs that isolates damage in removable steel dampers and uses in parallel viscous fluid dampers to reduce drifts has been proposed by Karavasilis et al. (2012b). A study shows that supplemental viscous damping does not always ensure adequate reduction of residual drifts (Karavasilis and Seo 2011). A recent work evaluates the seismic collapse resistance of steel MRFs with viscous fluid dampers and shows that supplemental viscous damping does not always guarantee a better seismic collapse resistance when the strength of the steel MRF with dampers is lower or equal to 75 % of the strength of a conventional steel MRF (Seo et al. 2014).

In the following section, two major real-world applications of passive dampers in a tall building and a bridge are briefly discussed. The most common types of passive dampers and the models used to simulate their hysteretic behavior are then presented. Finally, the analysis methods that can be utilized to predict the response of structures with passive dampers are discussed.

Application of Passive Dampers in Buildings and Bridges

Two relatively recent applications of passive dampers in a building and a bridge are discussed below.

Buildings and Bridges Equipped with Passive Dampers Under Seismic Actions: Modeling and Analysis, Fig. 1 (a) Torre Mayor Tower under

construction showing partial view of megabraces; (b) view of installed viscous fluid dampers (Symans et al. 2008)

Torre Mayor Tower, Mexico

The Torre Mayor Tower is a 77,000 m², 57-story steel and reinforced concrete office/hotel tower in Mexico City. Its construction was completed in 2003 and its height is 225 m. The lower half of the superstructure is a rectangular tower which consists of steel framing encased in concrete, while the upper half consists of steel framing (Fig. 1a). The seismic design of the structure had the challenging objective of achieving “operational” performance for an expected 8.2 magnitude seismic event (Rahimian and Romero 2003). The seismic design employs 96 large nonlinear viscous fluid dampers with 2,670 and 5,340-kN force output capacities (Fig. 1b). The dampers on the faces of the building are installed in megabraces, which are diagonal braces that span over more than one story, as shown in Fig. 1a. Note that, a first design of the building without dampers resulted in weight of the building that was excessive for the soil capacity. The addition of the dampers resulted in less steel weight and acceptable soil bearing pressure. The structure experienced no damage during a seismic event with 7.8

magnitude and epicenter 500 km from the building site (Rahimian and Romero 2003).

Rion-Antirion Bridge, Greece

The Rion-Antirion Bridge (Fig. 2), that crosses the homonymous strait in Greece, is located in the very active seismic region of the Gulf of Corinth. The deck of this multi-span cable-stayed bridge is continuous and fully suspended from four pylons (total length of 2,252 m). Its approach viaducts comprise 228 m of concrete deck on the Antirion side and 986 m of steel composite deck on the Rion side. Said structures are designed to withstand seismic events generating ground accelerations of up to 0.48 g through the use of viscous fluid dampers and other seismic devices. The Main Bridge seismic protection system consists of fuse restraints and viscous fluid dampers that act in parallel, connecting the deck to the pylons (Fig. 2b). The fuse restraints are designed as a rigid link intended to withstand high wind loads up to a predetermined force. Under the action of the design earthquake, the fuse restraints will fail and leave the dampers free to dissipate the semi

under construction; (b) arrangement of viscous fluid dampers and fuse restraints on the main piers (Infanti et al. 2004)

induced energy. The approach viaducts are seismically isolated utilizing elastomeric isolators and viscous dampers.

Passive Dampers and Constitutive Models

Passive dampers can be classified in three main categories: (1) velocity-activated or rate-dependent, (2) displacement-activated or rate-independent, and (3) motion-activated (Symans et al. 2008; Christopoulos and Filiatrault 2006).

Velocity-activated or rate-dependent dampers have force output that depends on the relative velocity across the damper. Therefore, their efficiency to dissipate energy depends on the frequency of the input ground motion. The behavior of such dampers is commonly described using various models of linear viscoelasticity. Typical dampers falling in this category include viscous fluid dampers and viscoelastic dampers (Symans et al. 2008; Christopoulos and Filiatrault 2006).

Displacement-activated or rate-independent dampers have force output that does not depend on the relative velocity across the damper but on the magnitude of the displacement and possibly the direction of motion. Their behavior is

commonly described using various nonlinear hysteretic models. Typical dampers falling in this category include metallic dampers and friction dampers (Symans et al. 2008; Christopoulos and Filiatrault 2006).

Motion-activated passive dampers consist of secondary systems that disturb the flow of energy in the structure. These systems have the same resonance period with the main structure. Tuned-mass dampers (TMDs) are an example of motion-activated dampers. This last category is not discussed further in this contribution, but the reader is referred to documents such as the one by Soong and Spencer (2002) for more details.

A summary of velocity-activated and displacement-activated passive dampers is provided in Fig. 3 (reproduced from Symans et al. (2008)). Figure 3 lists the basic construction, the idealized hysteretic response and the associated physical model, and the major advantages and disadvantages of each passive damper.

Viscous Fluid Dampers

Viscous fluid dampers consist of a hollow cylinder filled with fluid (Fig. 3), the fluid typically being silicone based. As the damper piston rod and piston head are stroked, fluid is forced to flow through orifices either around or through the piston head. The resulting differential in pressure

	Viscous Fluid Damper	Viscoelastic Solid Damper	Metallic Damper	Friction Damper
Basic Construction				
Idealized Hysteretic Behavior				
Idealized physical Model			Idealized Model Not Available	
Advantages	- Activated at low displacements - Minimal restoring force - For linear damper, modeling of damper is simplified - Properties largely frequency and temperature-independent - Proven record of performance in military applications	- Activated at low displacements - Provides restoring force - Linear behavior, therefore simplified modeling of damper	- Stable hysteretic behavior - Long-term reliability - Insensitivity to ambient temperature - Materials and behavior familiar to practicing engineers	- Large energy dissipation per cycle - Insensitivity to ambient temperature
Disadvantages	- Possible fluid seal leakage (reliability concern)	- Limited deformation capacity - Properties are frequency and temperature-dependent - Possible debonding and tearing of VE material (reliability concern)	- Device damaged after earthquake; may require replacement - Nonlinear behavior; may require nonlinear analysis	- Sliding interface conditions may change with time (reliability concern) - Strongly nonlinear behavior; may excite higher modes and require nonlinear analysis - Permanent displacements if no restoring force mechanism provided

Buildings and Bridges Equipped with Passive Dampers Under Seismic Actions: Modeling and Analysis, Fig. 3 Summary of basic construction,

hysteretic behavior, physical models, advantages, and disadvantages of passive dampers for seismic protection applications (Symans et al. 2008)

across the piston head can produce very large forces that resist the relative motion of the damper. The fluid flows at high velocities, resulting in the development of friction between

fluid particles and the piston head, which leads to energy dissipation in the form of heat. Interestingly, although the damper is called a *viscous fluid damper*, the fluid typically has a relatively

Buildings and Bridges Equipped with Passive Dampers Under Seismic Actions: Modeling and Analysis,

Fig. 4 Hysteretic behavior of a nonlinear viscous damper from nonlinear dynamic analysis (Karavasilis et al. 2012b)

low viscosity, e.g., silicone oil with a kinematic viscosity in the order of $0.001 \text{ m}^2/\text{s}$ at 20°C . The term *viscous fluid damper* is associated with the macroscopic behavior of the damper, which is essentially the same as that of an ideal linear or nonlinear viscous dashpot, i.e., the resisting force is directly related to the velocity (Symans et al. 2008).

Experimental testing (Seleemah and Constantinou 1997) has shown that the behavior of viscous fluid dampers corresponds to a nonlinear viscous dashpot and can be modeled by the following nonlinear force-velocity relation:

$$P(t) = C|\dot{u}(t)|^a \text{sgn}[\dot{u}(t)] \quad (1)$$

where $P(t)$ is the force developed by the damper, $u(t)$ is the displacement across the damper, C is damping coefficient, a is an exponent whose value is determined by the piston head orifice design, $\text{sgn}[\cdot]$ is the signum function, and the overdot indicates differentiation with respect to time, t . For earthquake protection applications, the exponent a typically has a value ranging from about 0.3 to 1.0. For a equal to unity, the damper can be described as an ideal linear viscous dashpot (Symans et al. 2008). Figure 4 shows the behavior of a nonlinear viscous damper installed in a prototype steel building subjected to a strong earthquake ground motion from nonlinear dynamic analysis conducted in Karavasilis et al. (2012b).

Viscoelastic Solid Dampers

Viscoelastic solid dampers generally consist of solid elastomeric pads (viscoelastic material)

bonded to steel plates, which are attached to the structure within chevron or diagonal bracing (Fig. 3). As one end of the damper displaces with respect to the other, the viscoelastic material is sheared resulting in the development of heat, which is dissipated to the environment. Viscoelastic dampers provide both a velocity-dependent force, which provides supplemental viscous damping to the system (similar to viscous dampers), and a displacement-dependent elastic restoring force (Symans et al. 2008).

Experimental testing (Bergman and Hanson 1993) has shown that, under certain conditions, a suitable mathematical model for simulating the mechanical behavior of viscoelastic dampers is the Kelvin model of viscoelasticity. This model is described by the following equation:

$$P(t) = Ku(t) + C\dot{u}(t) \quad (2)$$

where K is the storage stiffness of the damper and C is the damping coefficient which is equal to the ratio of the loss stiffness to the frequency of loading. The physical model corresponding to Eq. 2 is a linear spring in parallel with a linear viscous dashpot.

A constitutive model that can be used to describe with more accuracy the behavior of viscoelastic dampers is the generalized Maxwell (GM) model. The GM model consists of a parallel combination of a linear spring, a dashpot and multiple in-series combinations of springs and dashpots as shown in Fig. 5 (Karavasilis et al. 2011b). Figure 5 shows the GM model in terms of shear stress, τ , and shear strain, γ , of the viscoelastic material. Under harmonic loading of

cyclic frequency ω , the GM model provides storage shear modulus equal to

$$G'(\omega) = G_0 + \sum_{m=1}^n \frac{(\omega\beta_m)^2}{1 + (\omega\beta_m)^2} \cdot G_m \quad (3)$$

and loss factor equal to

$$\eta(\omega) = \frac{(\omega\beta_0)G_0 + \sum_{m=1}^n \frac{(\omega\beta_m)}{1 + (\omega\beta_m)^2} \cdot G_m}{G_0 + \sum_{m=1}^n \frac{(\omega\beta_m)^2}{1 + (\omega\beta_m)^2} \cdot G_m} \quad (4)$$

These equations can be used to calibrate the GM model against experimentally obtained values of G' and η for different cyclic frequencies. To use the GM model as a combination of linear springs and dashpots within a structural analysis

Buildings and Bridges Equipped with Passive Dampers Under Seismic Actions: Modeling and Analysis,

Fig. 6 Hysteretic behavior of viscoelastic damper from nonlinear dynamic analysis (Fan 1998)

software, simply multiply G_0 and G_m in Fig. 5 with the ratio A_d/t_d (A_d : horizontal area of the viscoelastic material; t_d : thickness of the viscoelastic material) to transform τ - γ behavior to force ($F = \tau \cdot A_d$) – deformation ($d = \gamma \cdot t_d$) behavior.

Figure 6 shows the hysteretic behavior of a typical viscoelastic damper from nonlinear dynamic analysis conducted in Fan (1998).

Metallic Dampers

Metallic dampers are designed to yield, based on the ability of steel to dissipate energy. Two major types of metallic dampers are the buckling-restrained brace (BRB) and the added damping and stiffness (ADAS) device.

A BRB consists of a steel brace with a cruciform cross section that is surrounded by a stiff steel tube. The region between the tube and brace is filled with a concrete-like material and a special coating is applied to the brace to prevent it from bonding to the concrete. Thus, the brace can slide with respect to the concrete-filled tube. The confinement provided by the concrete-filled tube allows the brace to be subjected to compressive loads without buckling. Under compressive loads, the BRB behavior is essentially identical to its behavior in tension. Since buckling is prevented, significant energy dissipation can occur over a cycle of motion (Symans et al. 2008).

The ADAS damper (Whittaker et al. 1991) consists of a series of steel plates wherein the

bottom of the plates are attached to the top of a chevron bracing arrangement and the top of the plates are attached to the floor level above the bracing. As the floor level above deforms laterally with respect to the chevron bracing, the steel plates are subjected to a shear force. The shear force induces bending moments over the height of the plates, with bending occurring about the weak axis of the plate cross section. The geometrical configuration of the plates is such that bending moments produce a uniform flexural stress distribution over the height of the plates so that inelastic action occurs uniformly over the full height of the plates. For example, in the case that the plates are fixed-pinned, the geometry is triangular; however, if the plates are fixed-fixed, the geometry is an hourglass shape.

Other types of metallic dampers have been developed for beam-column connections, braces and base isolation systems. Early developments include the U-strip hysteretic dampers and the T-ADAS damper. Other examples include the honeycomb damper used as seismic isolation system in bridges, C-shaped and E-shaped hysteretic dampers for bridges, slit-type dampers applied to beam-column connections or brace members, yielding shear panels, cast-iron yielding fuses installed in braces and hourglass shape pins installed in beam-column connections. A complete reference list for the aforementioned metallic dampers is provided in Vasdravellis et al. (2014).

Various mathematical models that describe yielding behavior of metals can represent the hysteretic behavior of metallic dampers such as the standard Bouc-Wen model (Wen 1976). The standard Bouc-Wen model results from the parallel combination of an elastic component and an

elastic-perfectly plastic component. The force output F of the model is

$$F = pku + (1 - p)F_y z \quad (5)$$

where u is the deformation across the model, F_y the yield force, k the elastic stiffness, p the post-yield stiffness ratio, and z a dimensionless hysteretic parameter governed by

$$\dot{z} = \frac{k}{F_y} \dot{u} [1 - |z|^n (\beta \text{sgn}[\dot{u}z] + \gamma)] \quad (6)$$

where β and γ are parameters controlling the shape of the hysteresis, n is a parameter that controls the sharpness of the smooth transition from the elastic to the inelastic region of the hysteresis, $\text{sgn}[\cdot]$ is the signum function, and the overdot denotes derivative with respect to time.

Equation 5 shows that the Bouc-Wen model accounts for kinematic hardening (i.e., post-yield force increases with increasing deformation) due to the post-yield stiffness ratio p . However, the model does not account for the isotropic hardening (i.e., yield force F_y increases due to cyclic inelastic deformation) in the hysteresis of steel energy dissipation devices.

To account for isotropic hardening in the Bouc-Wen model, the mathematical formulation developed by Karavasilis et al. (2012b) is described below:

The yield force F_y needs to be updated by considering the history of the imposed cyclic deformation u . Examination of the constitutive Eqs. 5 and 6 reveals that a change in the yield force F_y can be achieved by appropriately including a third shape control parameter Φ in Eq. 6:

$$\dot{z} = \frac{k}{F_y} \dot{u} \left[1 - |z|^n \left(\beta \text{sgn}(\dot{u}z) + \gamma - \frac{\Phi \text{sgn}(\dot{u})(\text{sgn}(z) + \text{sgn}(\dot{u}))}{\text{sgn}(\dot{u})} \right) \right] \quad (7)$$

The parameter Φ quantifies isotropic hardening and is calculated using functions that cause Φ to increase exponentially with increasing cumulative plastic deformation $u_{pl,c}$, i.e.,

$$\Phi_p = \Phi_{\max,p} \left[1 - \exp \left(-p_{\Phi,p} \left| \frac{u_{pl,c}}{u_y} \right| \right) \right] \quad (8a)$$

or

Buildings and Bridges Equipped with Passive Dampers Under Seismic Actions: Modeling and Analysis, Fig. 7 Results from the modified Bouc-Wen

model proposed in Karavasili et al. (2012b) and experimental results for a low-yield-strength shear panel and a BRB

$$\Phi_n = \Phi_{\max, n} \left[1 - \exp \left(-p_{\Phi, n} \left| \frac{u_{pl, c}}{u_y} \right| \right) \right] \quad (8b)$$

where $u_y (= F_y/k)$ is the yield deformation, $p_{\Phi, p}$ and $p_{\Phi, n}$ are parameters that control the isotropic hardening rate due to cumulative plastic deformation, and $\Phi_{\max, p}$ and $\Phi_{\max, n}$ are the maximum possible values of Φ for the fully saturated isotropic hardening condition, i.e., for $u_{pl, c} \rightarrow \infty$, $\Phi_p \rightarrow \Phi_{\max, p}$ and $\Phi_n \rightarrow \Phi_{\max, n}$. On the other hand, when $u_{pl, c} = 0.0$, $\Phi_p = 0.0$ and $\Phi_n = 0.0$.

Φ_p and Φ_n are used to independently capture isotropic hardening in different loading directions (positive and negative). Typically, yielding devices exhibit the same isotropic hardening in different loading directions, and therefore, $\Phi_{\max, p} = \Phi_{\max, n}$ and $p_{\Phi, p} = p_{\Phi, n}$. However, the model can simulate different isotropic hardening in different loading directions (e.g., compressive and tensile loading in BRB hysteresis) by using different parameter values in Eqs. 8a and 8b.

To understand the effect of Φ , consider the proposed Bouc-Wen model with $p = 0.0$ (i.e., without kinematic hardening), $n = 1$ and $\beta + \gamma = 1$, under a positive deformation increment, i.e., $\text{sgn}[\dot{u}] = 1$. Assume that in the previous deformation increment, z has reached its positive ultimate value z_u , and therefore, $\text{sgn}[z] = 1$ and $\dot{z} = 0.0$. For this case, Eq. 7 yields $z_u = 1/(1 - 2 \cdot \Phi)$ and Eq. 5 yields $F = F_y \cdot z_u = F_y/(1 - 2 \cdot \Phi)$. When $\Phi = 0.0$ (i.e., without isotropic hardening), F is equal to $F_y/(1 - 0.0) = F_y$. When $\Phi \neq 0.0$ (e.g., $\Phi = 0.1$), F is equal to $F_y/(1 - 2 \cdot 0.1) = F_y/(1 - 2 \cdot 0.1) = 1.25 \cdot F_y$. In that case, Φ

reflects a 25 % increase in the initial yield strength F_y due to isotropic hardening. The term $\text{sgn}[\dot{u}]$ after the parameter Φ in Eq. 7 ensures that the above calculations apply to the case of a negative deformation increment and a negative ultimate value of z .

The state determination procedure requires as an input the previous force and deformation, the previous z value, and the current deformation. The current value of the parameter Φ is then calculated based on the following rules: Eq. 8a is used to update Φ_p when the deformation increment changes from negative to positive within the plastic region of the hysteresis; Eq. 8b is used to update Φ_n when the deformation increment changes from positive to negative within the plastic region of the hysteresis; Φ equals to Φ_p when a positive deformation increment occurs; and Φ equals to Φ_n when a negative deformation increment occurs. With the current Φ value known, Eq. 7 is numerically integrated to obtain the current value of z which is simply used in Eq. 5 to provide the current force output F of the model.

Figure 7 shows how the aforementioned modified Bouc-Wen model captures the behavior of low yield strength shear panels showing significant isotropic hardening in their hysteresis as well as the behavior of BRBs showing different isotropic hardening in tension and compression.

Friction Dampers

Friction dampers dissipate seismic energy by friction that develops between two solid bodies sliding relative to one another. Typical friction

dampers are slotted-bolted (Grigorian et al. 1993), where a series of steel plates are bolted together with a specified clamping force. The clamping force is such that slip occurs at a pre-specified friction force. Another configuration is the Pall friction damper, which consists of cross bracing that connects in the center to a rectangular damper (Pall and Marsh 1982). The damper is bolted to the cross bracing and, under lateral load, the structural frame distorts such that two of the braces are subjected to tension and the other two to compression. This force system causes the rectangular damper to deform into a parallelogram, dissipating energy at the bolted joints via sliding friction (Symans et al. 2008).

Experimental testing (Pall and Marsh 1982) has shown that the idealized Coulomb friction model can model the behavior of friction dampers, i.e., the force output of friction dampers is given by

$$P(t) = \mu N \text{sgn}[\dot{u}(t)] \quad (9)$$

where μ is the coefficient of dynamic friction and N is the normal force at the sliding interface.

Analysis Methods for Buildings and Bridges with Passive Dampers

The analysis methods used to predict the response of buildings and bridges equipped with passive dampers are classified in two categories: (1) linear analysis methods and (2) nonlinear analysis methods.

Linear Analysis Methods

All linear analysis methods for structures equipped with rate-dependent passive dampers involve a simplified calculation of the supplemental (equivalent) damping ratio, ξ_{eq} . For example, given the damping coefficients C_i at each story i of a building and by assuming linear fluid viscous dampers ($a = 1$ in Eq. 1) positioned in a horizontal configuration, ξ_{eq} at the fundamental period of vibration T_1 under elastic conditions can be estimated as (Whittaker et al. 2003):

$$\xi_{eq} = \frac{T_1}{4\pi} \times \frac{\sum_i C_i (\phi_i - \phi_{i-1})^2}{\sum_i m_i \times \phi_i^2} \quad (10)$$

where ϕ_i and ϕ_{i-1} are the first modal displacements of stories i and $i - 1$, respectively, and m_i is the mass of story i . Equation 10 assumes that the braces supporting the dampers are stiff enough (essentially rigid) so that story deformation results in damper deformation rather than brace deformation. Alternative equations that take into account the effect of the brace flexibility on ξ_{eq} are provided for various brace-damper configurations in Hwang et al. (2008).

ξ_{eq} is used to calculate the damping reduction factor, which is then utilized to appropriately reduce the ordinates of the elastic response spectrum. This reduced highly damped spectrum is used to estimate the response of the structure with dampers. Lin and Chopra (2003) have evaluated the premise that the peak displacement of an elastic SDOF system with a natural period T_n and equipped with a viscous damper (damping coefficient C) in series with a brace of stiffness K_b , can be estimated by a linear viscous SDOF system with the same period T_n along with a simplified calculation of the added damping ratio (see Eq. 10). This premise was found valid for SDOF systems with $\tau/T_n < 0.02$, where τ is the relaxation time, i.e., $\tau = C/K_b$. As discussed by Lin and Chopra (2003), the relation $\tau/T_n < 0.02$ is satisfied for the practical range of values for the bracing axial stiffness K_b and the damping coefficient C . Therefore, the damper and brace properties necessary to ensure that elastic drift demands do not exceed a prescribed design limit can be determined using the reduced elastic design spectrum associated with the equivalent damping ratio.

In the 2003 *NEHRP Recommended Provisions* (BSSC 2004) for buildings with passive dampers, and for the equivalent lateral force (ELF) analysis (linear static analysis) specifically, the response is defined by two modes: the fundamental mode and the residual mode, which is used to approximate the combined effects of higher modes. For response spectrum analysis, higher modes are

Buildings and Bridges Equipped with Passive Dampers Under Seismic Actions: Modeling and Analysis, Fig. 8 Idealized elastoplastic pushover curve used for linear analysis (Symans et al. 2008)

explicitly evaluated. For both the ELF and the response spectrum analysis procedures, the shape of the fundamental-mode pushover capacity curve is not known and an idealized elastoplastic pushover curve is assumed, as shown in Fig. 8. Note that, in Fig. 8, the parameters Γ_1 and S_{DS} , which are used to compute the design earthquake displacement, D_{ID} , represent the modal participation factor for the fundamental mode and the 5 % damped design spectral response acceleration at short periods, respectively. The idealized pushover curve permits defining the effective global ductility demand due to the design earthquake, μ_D , as the ratio of design roof displacement, D_{ID} , to the yield displacement, D_Y . This ductility factor is used to calculate various design factors and to limit the maximum ductility demand, μ_{max} , in a manner that is consistent with conventional building response limits. Passive dampers should be designed for actual fundamental-mode design earthquake forces corresponding to a base shear value of V_Y , while the elements of the seismic-force-resisting system be designed for a reduced fundamental-mode base shear, V_1 , where the force reduction is based on system overstrength, Ω_0 (Symans et al. 2008).

A simplified linear method of analysis for building frames with elastomeric or viscoelastic dampers has been proposed by Lee et al. (2009) and has been recently extended to the case of fluid viscous dampers by Seo et al. (2014). This method is fully compatible with linear methods

of analysis used for conventional lateral load resisting systems in seismic codes and adopts the use of the strength reduction factor to calculate the required design base shear and the displacement amplification factor to estimate drifts.

Nonlinear Analysis Methods

The 2003 *NEHRP Recommended Provisions* (BSSC 2004) specify procedures for nonlinear static analysis and nonlinear dynamic (response-history) analysis. The nonlinear static analysis procedure is similar to the ELF procedure, in that the pushover capacity curve is used to define the nonlinear behavior of the structure. However, in the nonlinear static analysis procedure, the actual nonlinear force-displacement relation is used, rather than an idealized elastoplastic curve. In addition, since actual pushover strength is known from the nonlinear pushover analysis, the force reduction for design of the seismic-force-resisting system is based on overstrength alone with no additional reduction (Symans et al. 2008).

In general, the nonlinear dynamic analysis procedure is the most robust procedure available for evaluating the behavior of structures with passive dampers. It allows explicit modeling of individual devices, the elements connecting the devices to the structure, and the structure itself. If the connecting elements or the structural framing yields during the response, this behavior must be incorporated into the analytical model.

It is noted that accurate modeling of the flexibility of the floor diaphragm and of the connecting elements (braces) is essential since a loss of effective damping may occur if these elements are overly flexible.

Nonlinear dynamic analysis may be performed using a variety of commercially available software. In addition, there are several *academic* programs available, such as DRAIN-2DX (Prakash et al. 1993) and OpenSees (Mazzoni et al. 2006). Most of these programs can readily be used to model the behavior of linear fluid viscous dampers, viscoelastic dampers, friction dampers, or metallic yielding dampers. However, modeling of some damping devices (e.g., nonlinear viscous dampers and dampers with temperature-dependent or frequency-dependent mechanical properties) can be more challenging or, in some cases, not possible with a given program.

When nonlinear dynamic analysis is used, it is often beneficial to investigate the sensitivity of the structure response to one or more systemic parameters. Examples of parameters to vary include ground motion scaling parameters and parameters of the passive dampers (Symans et al. 2008).

Summary

The scope of this contribution was the presentation of numerical models and analysis methods used for structures equipped with passive dampers. The principal function of passive dampers and their application in buildings and bridges were discussed. The most common types of passive dampers and the constitutive models used to simulate their hysteretic behavior were presented. Finally, the analysis methods used for seismic design and assessment of structures with passive dampers were covered.

Cast Fuse Braces: Design and Implementation

Cast steel yielding brace system

Introduction

The yielding brace system (YBS) is a seismic-resistant bracing system for concentrically braced frame building structures designed at the University of Toronto (Gray et al. 2013). The YBS consists of a special yielding connector, or fuse, at the end of a concentric steel brace. When large lateral earthquake forces are imposed on a building designed with the YBS, the connector's specially designed triangular fingers yield in flexure. The yielding of the fingers dissipates seismic energy and limits the forces that the remaining structural elements must resist. This is analogous to the fuse in an electric circuit, which is why the yielding connector is sometimes called a "fuse."

Yielding connectors are comprised of two castings which are connected to the end of a brace member. Each casting includes an elastic arm portion with a series of triangular yielding fingers. The ends of the yielding fingers are

bolted to a fabricated splice plate assembly which is connected to a standard beam-column gusset plate connection. A YBS prototype is illustrated in a full-scale frame test configuration in Fig. 1.

Much like the TADAS system (Tsai et al. 1993), the fingers are triangular to promote yielding along their entire length. The bending moment diagram of each finger is triangular, like a cantilever. The triangular shape of the finger ensures that moment resistance diagram matches the applied moment diagram and the extreme fiber of the finger yields simultaneously at all points along the length of the finger.

The yielding fingers are connected to a fabricated plate assembly via slotted holes. The slotted holes enable the end of the finger to translate in the direction that is normal to the brace axis as the finger is deformed. A standard hole would restrain that movement and cause large axial forces, and strains, to develop in the fingers, which would decrease their displacement capacity.

Nonlinear Response

The YBS yielding connector exhibits a full, ductile hysteretic response. A sample hysteresis of the YBS is presented in Fig. 2. The stiffness and displacement capacity of the braces and connectors have been demonstrated to be very similar to other high-ductility braces, like the buckling

Cast Fuse Braces: Design and Implementation,
Fig. 1 YBS prototype in a full-scale frame test

Cast Fuse Braces: Design and Implementation,
Fig. 2 Sample hysteresis of a YBS brace

restrained brace. However, unlike the buckling restrained brace (► [Buckling-Restrained Braces and Their Implementation in Structural Design of Steel Buildings](#)) which has a higher strength in compression than in tension, the YBS has a symmetric response.

Another difference between the two systems is the post-yield response of the YBS. Although the slotted holes, to which the fingers are bolted, reduced the axial forces that develop in the fingers at large displacements, some axial force develops due to the finger's second-order

deformed shape. The small axial force appears in the connector's global response as distinct increase in strength and stiffness at large displacements. The benefit of such a response, when considered in the structural design, is the ability to limit the amount of inelastic demand that can concentrate on a single story of a multistory building. As the lateral deformation of a single story increases, the brace eventually increases in strength, thereby forcing adjacent stories to become engaged and inelastic demand to spread up the height of the building.

Design

To best take advantage of the economies available in the casting process, YBS connectors are available in a series of off-the-shelf configurations for a variety of brace yield loads. The intention is that each available connector size will have an associated maximum brace elongation and brace rotation for which it has successfully completed the testing requirements of Section K3 of AISC 341-10 (AISC 2010).

A designer wishing to utilize the YBS in a building design first selects the appropriate connector for each brace based on strength requirements. As fuse connectors are generally available in force increments of approximately 10 %, any overstrength due to the incremental nature of the YBS is small.

Like all traditional earthquake-resistant steel structures, elements of the lateral force-resisting system which are intended to remain elastic are capacity designed for the expected strength of the yielding element. The adjusted brace strength is the product of three parameters: the nominal connector yield strength, P_y ; material overstrength, R_y ; and the overstrength resulting from cyclic strain hardening and the geometric post-yield stiffening effect, ω .

The nominal connector yield strength is directly computed using the sum of plastic flexural strengths of the connector's yielding fingers, the length of each finger, and minimum allowable yield strength of the cast steel material.

Past experience with manufacture of steel castings (Gray 2012) has indicated that cast steel yield strength can be well controlled through a well-defined heat treatment process. An assumed material overstrength of 1.1 is easily achieved through standard foundry practices and can be verified by tensile coupon testing.

The effect of cyclic strain hardening and post-yield stiffening, ω , can be measured directly through full-scale testing. As the fuse's adjusted strength is determined for an elongation of $2\Delta_{bm}$ (the elongation associated with greater of twice the design level drift or 2 %), the overstrength factor, ω , is the ratio of the force measured during cyclic testing at this deformation to the yield

force determined using the actual material yield strength of the test specimen.

Once the connector sizes are selected and the adjusted brace strength is calculated, the brace members must be designed. Generally, YBS fuse connectors are used with W-section or rectangular/square hollow structural section braces. Brace design is governed by the factored compressive resistance of the brace member, which must exceed the adjusted strength of the yielding connector. The in-plane and out-of-plane effective buckling lengths are different for yielding connector equipped braces. Out of plane, the connector provides continuous stability such that the effective length can be taken as the work point-to-work point length of the brace member. In plane, the yielding finger-to-slotted hole connection provides very little rotational or lateral stiffness, and the brace can be idealized in plane as a flagpole. Thus it is recommended that the in-plane effective buckling length of the brace be determined from the distance from the center of the yielding finger-to-plate assembly connection to the opposite brace end connection with an effective length factor of 2.0. For stability, this requires that the opposite end brace connection provide in-plane flexural stiffness.

After the initial brace design is complete, the lateral stiffness of the building can be evaluated. In order to check drift limits, to conduct a linear response spectrum analysis, or to run a nonlinear dynamic analysis, the total brace stiffness must be calculated. The flexibility of a brace equipped with a yielding connector is determined by summing the flexibilities of the connector and the brace itself. Since the design force for the brace (the adjusted strength of the connector) is determined based on the design story drift, which is a function of the brace stiffness, brace design may be an iterative process. If the initial brace flexibility is higher than expected, the design story drift and adjusted brace strength will also increase, potentially requiring a stronger brace.

With the use of yielding connectors, a structure's lateral stiffness can be increased through the use of heavier brace members, without increasing the brace yield force. Thus, there is not an increase in capacity design forces for

beams, columns, diaphragms, connections, or foundations that is often the case when increasing the stiffness of other traditional lateral force-resisting systems. This may be of particular relevance for structures with strict drift control limits.

Like a buckling restrained braces, bracing connections are to be designed for a force of 1.1 times the adjusted brace strength. Connections can be field bolted or field welded, provided that the connection on the opposite side of the brace from the yielding connector provides in-plane flexural stiffness.

As with other high-ductility lateral force-resisting systems, the beams, columns, diaphragms, and foundations should all be designed with capacity design principles for the adjusted brace strength of the final braced frame design.

Replace-Ability

Replace-ability is a newer concept in earthquake engineering that involves detailing the yielding element of a seismic force-resisting system to be easily removed and replaced after a significant earthquake event. If a seismic lateral force-resisting system is properly designed and detailed, only a small part of the structure is damaged during an earthquake. If those elements are designed to be easily replaced, the post-earthquake repair cost for the building could be significantly less than with traditional seismic force-resisting systems. Replaceable elements have been designed and tested for eccentrically braced frames (Mansour et al. 2011) and moment-resisting frames (Shen et al. 2011). Replaceable eccentrically braced frames have been implemented in steel buildings in Christchurch, since the devastating earthquake of 2011.

The yielding brace system can be designed with bolted joints at both the connector-to-brace and connector-to-gusset plate connections. This enables relatively simple removal and replacement after a major earthquake. Of course the removal of the connectors is only necessary if they have undergone significant cyclic inelastic displacements. The state of a connector can be

easily evaluated post-earthquake, as all of the yielding elements are visible. After cycling at large displacements, but long before low-cycle fatigue failure, cracking becomes visible on the surfaces of the yielding fingers. This would enable the inspection and evaluation of a yielding connector after a major earthquake.

Retrofit

Although originally intended for using in new building structure, yielding connectors can be used as hysteretic dampers for the retrofit of seismically deficient existing structures (Retrofitting and Strengthening: An Overview). The full, symmetric hysteretic response of the yielding connectors provides the added damping that is desirable in many retrofit schemes. In addition, yielding connector equipped braces have a relatively high stiffness, which is beneficial when drift control is an issue, as it often is when retrofitting brittle, non-seismically designed structure.

The ability to modify a brace assembly's stiffness independently from its yield force (discussed in the Design section) is an attribute that is perhaps most valuable in a retrofit design. Excessive drift is a primary source of damage to existing structural elements in non-seismically detailed structures. As such, retrofit schemes often must limit drift during an earthquake to limit resulting damage. This is usually achieved through added stiffness; however, adding stiffness also requires simultaneously adding strength. Increasing the strength of the lateral force-resisting system increases the capacity design force that the existing structural elements must resist, often requiring expensive reinforcement of those elements.

The advantage offered by the YBS is that small connectors, which are stiff yet have large displacement capacities, can be used to provide hysteretic damping but limit the capacity design force the existing elements are required to resist. The brace member can then be selected to optimize the overall brace stiffness to control drifts and limit damage.

The post-yield stiffness of the YBS is valuable when used in deficient buildings with no other source of lateral stiffness. Seismic force-resisting systems with no post-yield stiffness, such as braces with friction dampers, are not suitable without a secondary source of lateral stiffness. On their own, such systems have a negative post-yield stiffness when second-order ($P-\Delta$) effects are considered. Unlike friction systems, the YBS can be used in cases with no other lateral stiffness, such as simple steel frames with unreinforced masonry walls, because of its characteristic post-yield stiffness.

Also, since the brace members are not part of the yielding element, they can have field splices, which enable easier installation in the existing building.

Summary

The yielding brace system (YBS) is a new high-ductility concentric bracing system that dissipates energy through the yielding of fingers within a special cast steel yielding connector. The connector has a full, symmetric hysteretic response that is characterized by a post-yield increase in strength and stiffness at large displacements. The design of systems using the yielding connectors is similar to the design of a buckling restrained brace: the connectors are selected for strength requirements and the remaining structural elements are capacity designed for the adjusted strength of the connector. Yielding connectors can be designed with bolted connections enabling simple post-earthquake replacement. They are suitable for both new buildings and for the retrofit of seismically deficient existing buildings.

Introduction

Characterization of damping forces in a vibrating structure has long been an active area of research in structural dynamics. The most common approach to model viscous forces is to use the

so-called viscous damping, first introduced by Lord Rayleigh (1877), which relies on the assumption that the damping matrix is a linear combination of the mass and stiffness matrices. Since its introduction, this model has been used extensively and is now usually known as *Rayleigh damping* or *classical damping* (Argyris and Mlejnek 1991; Clough and Penzien 1993). With such a damping model, the modal analysis procedure, originally developed for undamped systems, can be used to analyze damped systems in a very similar manner.

In reality, physical structures or systems are generally comprised of many substructures tied together in various fashions. These substructures can be made up of a variety of materials, i.e., metals, plastics, and woods. Furthermore, these substructures may be connected to one another by rivets, bolts, dampers, springs, friction, etc. Also, the spatial geometry of the structure may be very complicated. All of these factors influence the inherent dynamical properties of the structure. For these structures, mass, damping, and stiffness distribution (matrices) of the system are rather complicated. In general, for real-life structures, the damping matrix for such a system will not always be proportional to the mass and stiffness matrix.

For nonproportional damping, the well-known modal coordinate transformation, which diagonalizes the system mass and stiffness matrices, will not diagonalize the system damping matrix. Therefore, when a system with nonproportional damping exists, the equations of motion are coupled when formulated in n dimension physical space. Fortunately, the equations of motion can be uncoupled when formulated in $2n$ dimension state space, by means of complex analysis.

When dealing with earthquake excitation, the dynamic behavior of structural and mechanical systems subjected to uncertain dynamic excitations can be described, in general, through random processes (Chopra 1995). The probabilistic characterization of these random processes can be extremely complex, when nonstationary and/or non-Gaussian input processes are involved (Lin 1976). In specific applications, an incomplete description of stochastic processes corresponding to dynamic structural response

may suffice, based on the spectral characteristics of the processes under study (Priestley 1987). In particular, spectral characteristics can be employed to evaluate the time-variant central frequency and bandwidth parameters, which characterize in a synthetic way a nonstationary stochastic process. The spectral characteristic has been proved appropriate for describing nonstationary stochastic processes and can be effectively employed in structural reliability applications, such as the computation of the time-variant probability that a random process outcrosses a given limit-state threshold, and is useful for reliability of earthquake-sensible structures (Barbato and Conte 2008).

Classically Damped MDOF Structures

Free Vibrations of MDOF Structures

The free vibration equations of motion of an n -degree-of-freedom elastic structure are

$$\mathbf{M}\ddot{\mathbf{U}}(t) + \mathbf{K}\mathbf{U}(t) = 0 \quad (1)$$

where $\mathbf{M}$ and $\mathbf{K}$ are the $n \times n$ mass and stiffness symmetric and positive definite matrices, while $\mathbf{U}(t)$ is an n vector whose component collects the time-dependent response components of the structure. Equation 1 is a coupled system of n differential equations to be integrated with initial conditions

$$\dot{\mathbf{U}}(0) = \dot{\mathbf{U}}_0, \quad \mathbf{U}(0) = \mathbf{U}_0. \quad (2)$$

If the mass and stiffness matrices are positive definite, the solution of Eq. 1 can be written as

$$\mathbf{U}(t) = \sum_{j=1}^n C_j \exp(i\omega_j t) \phi_j \quad (3)$$

where C_j are n complex coefficients to be evaluated by imposing the initial conditions (Eq. 2), while ϕ_j and ω_j are, respectively, the *normal modes* and the *natural frequencies* of the structure, solution of the associated eigenvalue problem:

$$[\mathbf{K} - \omega_j^2 \mathbf{M}] \phi_j = \mathbf{0} \quad (4)$$

It can be shown that the orthogonality of the normal modes ϕ_j respects the stiffness and mass matrices (see, e.g., Clough and Penzien 1993). By setting with $\phi = [\phi_1 \dots \phi_n]$ the $n \times n$ modal matrix, whose column collects the normal modes of the structure, the following identity holds:

$$\phi^T \mathbf{M} \phi = \mathbf{I}, \quad \phi^T \mathbf{K} \phi = \mathbf{\Omega}^2 \quad (5)$$

In Eq. 5, $\mathbf{\Omega}$ is a diagonal matrix collecting the n natural frequencies of the structure, $\mathbf{\Omega} = [\omega_1 \dots \omega_n]$, while $\mathbf{I}$ is the identity matrix of order n .

Let us define the modal coordinates $\mathbf{q}(t)$ as

$$\mathbf{U}(t) = \phi \mathbf{q}(t) \quad (6)$$

Substituting Eq. 6 in Eq. 1 and left multiplying by ϕ^T , we obtain n uncoupled differential equation of motion in modal coordinates:

$$\ddot{\mathbf{q}}(t) + \mathbf{\Omega}^2 \mathbf{q}(t) = \mathbf{0} \quad (7)$$

which are the n uncoupled equations of motion in modal coordinates:

$$\ddot{q}_j(t) + \omega_j^2 q_j(t) = 0 \quad (8)$$

with associated solution

$$q_j(t) = q_j(0) \cos(\omega_j t) + \frac{\dot{q}_j(0)}{\omega_j} \sin(\omega_j t) \quad (9)$$

Using the orthogonality conditions (Eq. 5), the motion of the structure (Eq. 3) can be explicitly rewritten as follows:

$$\mathbf{U}(t) = \sum_{j=1}^n \left[\phi_j^T \mathbf{M} \mathbf{U}_0 \cos(\omega_j t) + \frac{\phi_j^T \mathbf{K} \dot{\mathbf{U}}_0}{\omega_j} \sin(\omega_j t) \right] \phi_j \quad (10)$$

Equation 10 shows that the free vibration of an n -dof structure can be thought as a linear combination of normal modes ϕ_j , each of them vibrating with the associated circular frequency ω_j .

Furthermore, giving an initial condition in displacement proportional to the j -th modes with zero velocity, the structure oscillates maintaining the shape of the given modes with circular frequency equal to ω_j .

Free Vibrations of Classically Damped MDOF Structures

The free vibration equations of motion of an n degree of freedom elastic structure with viscous damping are

$$\mathbf{M} \ddot{\mathbf{U}}(t) + \mathbf{C} \dot{\mathbf{U}}(t) + \mathbf{K} \mathbf{U}(t) = \mathbf{0} \quad (11)$$

where $\mathbf{C}$ is the $n \times n$ symmetric and positive definite damping matrix. An MDOF linear structure is *classically damped* if the damping matrix is diagonalizable by the modal matrix ϕ :

$$\phi^T \mathbf{C} \phi = [2\xi_1 \omega_1 \dots 2\xi_n \omega_n] = \mathbf{\Sigma} \quad (12)$$

In Eq. 12, ξ_i is the damping ratio of the i -th mode and ω_i is the undamped natural frequency of the i -th mode. The diagonal matrix $\mathbf{\Sigma}$ is called *modal damping matrix*. It is worth noting that for classically damped structural systems, the damping matrix $\mathbf{C}$ is diagonalizable by ϕ , which in turn depends only on $\mathbf{M}$ and $\mathbf{K}$, and is independent of $\mathbf{C}$ itself, regardless of how heavily the system is damped. There are many ways to compute a classical damping matrix from mass and stiffness matrices. A *Rayleigh* damping matrix is proportional to the mass and stiffness matrices:

$$\mathbf{C} = \alpha \mathbf{M} + \beta \mathbf{K} \quad (13)$$

where α and β are related to damping ratios and frequencies by

$$\xi_j = \frac{\alpha}{2\omega_j} + \frac{\beta\omega_j}{2} \quad (14)$$

An extended *Rayleigh* damping matrix, called *Caughey* damping matrix, can be computed from

$$\mathbf{C} = \mathbf{M} \left[\sum_{j=0}^{n-1} a_j (\mathbf{M}^{-1} \mathbf{K})^j \right] \quad (15)$$

where the a_j coefficients are related to damping ratios and frequencies by

$$\xi_k = \frac{1}{2} \sum_{j=0}^{n-1} a_j \omega_k^{2j-1}. \quad (16)$$

As for the free vibrations, the motion of an n -dof classically damped structure can be thought as a linear combination of normal modes ϕ_j , each of them vibrating with the associated circular frequency ω_j and damping ξ_j . Indeed, using the modal coordinates $\mathbf{q}(t)$ as defined in Eq. 6 and Eq. 11 and left multiplying by ϕ^T , we obtain n uncoupled differential equation of motion in modal coordinates:

$$\ddot{\mathbf{q}}(t) + \mathbf{\Sigma} \dot{\mathbf{q}}(t) + \mathbf{\Omega}^2 \mathbf{q}(t) = \mathbf{0} \quad (17)$$

which are the n uncoupled equations of motion in modal coordinates:

$$\ddot{q}_j(t) + 2\xi_j \omega_j \dot{q}_j(t) + \omega_j^2 q_j(t) = 0 \quad (18)$$

with associated solution

$$q_j(t) = e^{-\xi_j \omega_j t} \left(q_j(0) \cos(\bar{\omega}_j t) + \frac{\dot{q}_j(0) + \xi_j \omega_j q_j(0)}{\bar{\omega}_j} \sin(\bar{\omega}_j t) \right) \quad (19)$$

where $\bar{\omega}_j$ is the reduced or damped frequency of the j -th damped natural frequency and is related to the j -th undamped natural frequency and damping ratio by

$$\bar{\omega}_j = \omega_j \sqrt{1 - \xi_j^2}. \quad (20)$$

The response of the entire structure can be explicitly written as follows:

$$\mathbf{U}(t) = \sum_{j=1}^n \phi_j^T \mathbf{M} \left[\mathbf{U}_0 \cos(\bar{\omega}_j t) + \frac{(\dot{\mathbf{U}}_0 + \xi_j \omega_j \mathbf{U}_0)}{\bar{\omega}_j} \sin(\bar{\omega}_j t) \right] e^{-\xi_j \omega_j t} \phi_j \quad (21)$$

Equation 21 shows that the classically damped vibration of an n -dof structure can be thought as a linear combination of normal modes ϕ_j , each of them vibrating with the associated circular frequency ω_j and decaying with damping ξ_j .

Forced Vibrations of Classically Damped MDOF Structures

Let us consider the forced vibration equations of motion of an n degree of freedom elastic structure with classical viscous damping:

$$\mathbf{M} \ddot{\mathbf{U}}(t) + \mathbf{C} \dot{\mathbf{U}}(t) + \mathbf{K} \mathbf{U}(t) = \mathbf{f}(t) \quad (22)$$

where $\mathbf{f}(t)$ is the time-dependent n dimensional force vector. Equation 16 represents a system of n coupled linear differential equations to be solved with the initial conditions (Eq. 2). Using the modal coordinates $\mathbf{q}(t)$ transform, Eq. 6 and Eq. 22, and left multiplying by ϕ^T , because of the orthogonality conditions (Eqs. 5 and 12), the

following n uncoupled forced differential equation of motion in modal coordinates are obtained:

$$\ddot{\mathbf{q}}(t) + \mathbf{\Sigma} \dot{\mathbf{q}}(t) + \mathbf{\Omega}^2 \mathbf{q}(t) = \mathbf{p}(t) \quad (23)$$

having set

$$\mathbf{p}(t) = \phi^T \mathbf{f}(t) \quad (24)$$

to be solved with initial conditions

$$\mathbf{q}(0) = \phi^T \mathbf{U}(0), \quad \dot{\mathbf{q}}(0) = \phi^T \dot{\mathbf{U}}(0). \quad (25)$$

Equation 23 in explicit form becomes

$$\ddot{q}_j(t) + 2\xi_j \omega_j \dot{q}_j(t) + \omega_j^2 q_j(t) = p_j(t). \quad (26)$$

Solution of Eq. 26 can be split in the *homogenous* $q_j^0(t)$ and *particular* $q_j^p(t)$ integrals

$$q_j(t) = q_j^0(t) + q_j^p(t). \quad (27)$$

The homogenous solution depends only by the initial conditions and is given in Eq. 19, while the particular integral depends by the analytical form of the excitation and, for the rest initial conditions, can be simply written as

$$q_j^p(t) = \int_0^t h_j(t - \tau) p_j(\tau) d\tau. \quad (28)$$

In Eq. 28, the integral term is known as the *Duhamel integral*; the kernel of the integral $h_j(\cdot)$ is the response of the j -th oscillator as defined in Eq. 26 to an impulse idealized as Dirac's delta centered in $t = 0$ and is given by

$$h_j(t) = \frac{1}{\omega_j} e^{-\xi_j \omega_j t} \sin(\bar{\omega}_j t). \quad (29)$$

Vibrations of Classically Damped MDOF Structures in the Frequency Domain

Let us apply the Fourier transform operator to the force and response vectors:

$$\begin{aligned} \mathbf{F}(\omega) &= \int_{-\infty}^{+\infty} \mathbf{f}(t) e^{-i\omega t} dt, \\ \mathbf{Q}(\omega) &= \int_{-\infty}^{+\infty} \mathbf{q}(t) e^{-i\omega t} dt. \end{aligned} \quad (30)$$

It can be easily shown that applying the Fourier operator to both sides of Eq. 23, the following input–output relationship is found:

$$\mathbf{Q}(\omega) = \mathbf{H}_M(\omega) \phi^T \mathbf{F}(\omega). \quad (31)$$

In Eq. 31, $\mathbf{H}_M(\omega)$ is the *transfer modal matrix*, diagonal of order n , whose j -th element is given by

$$H_{Mj}(\omega) = \frac{1}{\omega_j^2 - \omega^2 + 2i\xi_j \omega_j \omega}. \quad (32)$$

Once $\mathbf{H}_M(\omega)$ is known, the nodal response transform

$$\mathbf{U}(\omega) = \int_{-\infty}^{+\infty} \mathbf{f}(t) e^{-i\omega t} dt \quad (33)$$

is given by

$$\mathbf{U}(\omega) = \mathbf{H}(\omega) \mathbf{F}(\omega). \quad (34)$$

In Eq. 34, $\mathbf{H}(\omega)$ is the *transfer matrix* of the structure of order n , defined as follows:

$$\mathbf{H}(\omega) = \phi \mathbf{H}_M(\omega) \phi^T = [\mathbf{K} - \omega^2 \mathbf{M} + i\omega \mathbf{C}]^{-1}. \quad (35)$$

Since $\mathbf{H}(\omega)$ is not diagonal, an easy to handle representation is

$$\mathbf{H}(\omega) = \sum_{j=1}^n \phi_j H_{Mj}(\omega) \phi_j^T. \quad (36)$$

Nonclassically Damped Vibrations of MDOF Structures

Nonclassically Damped Free Vibrations of MDOF Structures

When the damping is not classical, $\phi^T \mathbf{C} \phi$ is not a diagonal matrix. Under these circumstances, the natural frequencies, damping ratios, and modal vectors depend on the mass, stiffness, and damping matrices of the structural system. To determine the mode–shape vectors, natural frequencies, and damping ratios from $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$, it is convenient to write the second-order differential equation (Eq. 11) as two sets of first-order differential equations. Defining the velocity $\mathbf{V} = \dot{\mathbf{U}}$, so that $\dot{\mathbf{V}} = \ddot{\mathbf{U}}$, Eq. 11 can be rewritten as a set of two first-order differential equations in matrix form:

$$\frac{d}{dt} \begin{bmatrix} \mathbf{U} \\ \mathbf{V} \end{bmatrix} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1} \mathbf{K} & -\mathbf{M}^{-1} \mathbf{C} \end{bmatrix} \begin{bmatrix} \mathbf{U} \\ \mathbf{V} \end{bmatrix} \quad (37)$$

The matrix equation of motion Eq. 37 can be recast into the following first-order matrix equation:

$$\dot{\mathbf{Z}} = \mathbf{GZ} \quad (38)$$

where

$$\mathbf{Z} = \begin{bmatrix} \mathbf{U} \\ \dot{\mathbf{U}} \end{bmatrix}_{2n \times 1} \quad (39)$$

$$\mathbf{G} = \begin{bmatrix} \mathbf{0}_{n \times n} & \mathbf{I}_{n \times n} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix}_{2n \times 2n} \quad (40)$$

The subscripts in Eqs. 39 and 40 indicate the dimensions of the vectors and matrices to which they are attached. Solution of Eq. 38 can be written as

$$\mathbf{Z} = \mathbf{\Psi} e^{\lambda t}. \quad (41)$$

Substituting Eq. 41 in Eq. 38 returns the eigenvalue problem:

$$\mathbf{G}\mathbf{\Psi} = \lambda\mathbf{\Psi} \quad (42)$$

The eigenvalue problem in Eq. 42 admits $2n$ complex eigenvectors $\mathbf{\Psi}_j$ and complex eigenvalues $\lambda_j (j = 1, \dots, 2n)$ occurring in pair complex conjugate. It follows that each complex eigenvector $\mathbf{\Psi}_k$ with complex eigenvalue λ_k is associated with a complex conjugate eigenvector $\mathbf{\Psi}_k^*$ with complex conjugate eigenvalue $\lambda_k^* (k = 1, \dots, n)$.

Once the complex eigenvalues problem in Eq. 42 is solved, the solution of the equation of motion (Eq. 37) is given as follows:

$$\mathbf{U}(t) = \sum_{j=1}^{2n} C_j e^{\lambda_j t} \mathbf{\Psi}_j = 2 \sum_{j=1}^n \Re \{ C_j e^{\lambda_j t} \mathbf{\Psi}_j \}. \quad (43)$$

The $2n$ complex coefficients C_j depend on the initial conditions of motion and are given by

$$C_j = \mathbf{\Psi}_j^T (\lambda_j \mathbf{M} + \mathbf{C}) \mathbf{U}_0 + \mathbf{\Psi}_j^T \mathbf{M} \dot{\mathbf{U}}_0. \quad (44)$$

Vibrations of Nonclassically Damped MDOF Structures in the Frequency Domain

Applying the Fourier operator to both sides of the equation of motion in the nonclassically damped case, the following input–output relationship is found:

$$\mathbf{Q}(\omega) = \mathbf{H}_M(\omega) \phi^T \mathbf{F}(\omega) \quad (45)$$

In Eq. 45, $\mathbf{H}_M(\omega)$ is the $n \times n$ transfer modal matrix, for nonclassically damped systems non-diagonal, defined as follows:

$$\mathbf{H}_M(\omega) = [\mathbf{K} - \omega^2 \mathbf{M} + i\omega \mathbf{C}]^{-1}. \quad (46)$$

If the damping matrix $\mathbf{C}$ is decoupled in the sum of a diagonal matrix $\mathbf{C}_D$ collecting all the elements of the principal diagonal of $\mathbf{C}$ and a non-diagonal matrix $\mathbf{C}_F$ collecting the elements out of the principal diagonal of $\mathbf{C}$

$$\mathbf{C} = \mathbf{C}_D + \mathbf{C}_F \quad (47)$$

then defining the diagonal matrix $\mathbf{H}_D(\omega)$

$$\mathbf{H}_D(\omega) = [\mathbf{K} - \omega^2 \mathbf{M} + i\omega \mathbf{C}_D]^{-1}, \quad (48)$$

the following approximate representation holds:

$$\mathbf{H}_M(\omega) = \mathbf{H}_D(\omega) \left[\mathbf{I} + \sum_{j=1}^n (-i\omega)^j [\mathbf{C}_F \mathbf{H}_D(\omega)]^j \right] \quad (49)$$

Nonclassically Damped Vibrations of MDOF Structures Under Ground Excitation

A state-space formulation of the equations of motion for a linear *MDOF* system is useful to describe the response of both classically and nonclassically damped systems. The general (second-order) equations of motion for an n -degree-of-freedom linear structure under ground excitation are in matrix form:

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{C}\dot{\mathbf{U}} + \mathbf{K}\mathbf{U} = \mathbf{P}\mathbf{F}(t) \quad (50)$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are the $n \times n$ time-invariant mass, damping, and stiffness matrices, respectively; $\mathbf{U}(t)$ is the length- n vector of nodal displacements, $\mathbf{P}$ is the length- n load distribution vector, $\mathbf{F}(t)$ is the scalar function describing the time history of the external loading due to ground motion, and a superposed dot denotes differentiation with respect to time. The matrix equation of motion Eq. 50 can be recast into the following first-order matrix equation:

$$\dot{\mathbf{Z}} = \mathbf{G}\mathbf{Z} + \tilde{\mathbf{P}}\mathbf{F}(t) \quad (51)$$

where $\mathbf{Z}$ and $\mathbf{G}$ are defined in Eqs. 39 and 40, while $\tilde{\mathbf{P}}$ is given by

$$\tilde{\mathbf{P}} = \begin{bmatrix} \mathbf{0}_{n \times 1} \\ \mathbf{M}^{-1} \mathbf{P} \end{bmatrix}. \quad (52)$$

The subscripts in Eq. 52 indicate the dimensions of the vectors to which they are attached. Using the complex modal matrix $\mathbf{T}$ formed from the complex eigenmodes of matrix $\mathbf{G}$, the first-order differential matrix equation (Eq. 51) can be decoupled into the following $2n$ normalized complex modal equations:

$$\dot{S}_i(t) = \lambda_i S_i(t) + F(t), \quad i = 1, 2, \dots, 2n \quad (53)$$

where $\mathbf{S} = [S_1(t) S_2(t) \dots S_{2n}(t)]^T$ is a normalized complex modal response vector and $\lambda_i (i = 1, \dots, 2n)$ are the complex eigenvalues of the system matrix $\mathbf{G}$. The response of the linear MDOF system can be obtained as

$$\mathbf{Z}(t) = \mathbf{T} \mathbf{S}(t) = \tilde{\mathbf{T}} \mathbf{S}(t) \quad (54)$$

in which $\mathbf{\Gamma}$ = diagonal matrix containing the $2n$ modal participation factors Γ_i , defined as the i -th component of vector $\mathbf{T}^{-1} \tilde{\mathbf{P}} = [\Gamma_1 \dots \Gamma_{2n}]^T$, and $\tilde{\mathbf{T}} = \mathbf{T} \mathbf{\Gamma}$ = effective modal participation matrix. Assuming that the system is initially at rest, the solution of Eq. 53 can be expressed by the following Duhamel integral:

$$S_i(t) = \int_0^t e^{\lambda_i(t-\tau)} F(\tau) d\tau, \quad i = 1, 2, \dots, 2n \quad (55)$$

It is worth mentioning that the normalized complex modal responses $S_i(t)$, $i = 1, 2, \dots, 2n$ are complex conjugate by pairs.

Nonclassically Damped Forced Vibrations of MDOF Structures Under Earthquake Excitation

It is well known that the earthquake excitation can be represented as a nonstationary process, and a correct definition has to be addressed through the theory of stochastic process (Chopra 1995).

A nonstationary stochastic process (NSSP) $X(t)$ can be expressed in the general form of a Fourier–Stieltjes integral as (Priestley 1987)

$$X(t) = \int_{-\infty}^{\infty} A_X(\omega, t) e^{j\omega t} dZ(\omega) \quad (56)$$

where t is the time, ω is the frequency parameter, $j = \sqrt{-1}$, $A_X(\omega, t)$ is the complex-valued deterministic time-frequency modulating function, and $dZ(\omega)$ is the zero-mean orthogonal increment process defined so that $E[dZ^*(\omega_1) dZ(\omega_2)] = \Phi(\omega_1) \delta(\omega_1 - \omega_2) d\omega_1 d\omega_2$, where $E[\cdot]$ is the mathematical expectation, $\Phi(\omega)$ is the power spectral density (PSD) function of the embedded stationary process $X_S(t)$, $\delta(\cdot)$ is the Dirac delta function, and the superscript $(\cdot)^*$ denotes the complex-conjugate operator. If the process $X(t)$ is real valued, the following property holds:

$$A_X(-\omega, t) = A_X^*(\omega, t) \quad (57)$$

The process $X(t)$ has the following evolutionary power spectral density (EPSD) function:

$$\Phi_{X,X}(\omega, t) = A_X^*(\omega, t) \Phi(\omega) A_X(\omega, t) \quad (58)$$

In the case of a nonstationary loading process, the loading function $F(t)$ can be expressed as

$$F(t) = \int_{-\infty}^{\infty} A_F(\omega, t) e^{j\omega t} dZ(\omega). \quad (59)$$

It can be shown that the normalized complex modal responses are given by

$$S_i(t) = \int_{-\infty}^{\infty} A_{S_i}(\omega, t) e^{j\omega t} dZ(\omega), \quad i = 1, 2, \dots, 2n \quad (60)$$

where

$$A_{S_i}(\omega, t) = \int_{-\infty}^{\infty} e^{(\lambda_i - j\omega)(t-\tau)} A_F(\omega, \tau) d\tau, \quad i = 1, 2, \dots, 2n. \quad (61)$$

It is also convenient to define the process $Y(t)$ as the modulation (with modulating function

$A_X(\omega, t)$ of the stationary process $Y_S(t)$ defined as the Hilbert transform of the embedded stationary process $X_S(t)$, i.e.,

$$Y(t) = -j \int_{-\infty}^{\infty} \text{sign}(\omega) A_X(\omega, t) e^{j\omega t} dZ(\omega). \quad (62)$$

The cross variance between the response process $X(t)$ and the modulation process $Y(t)$ is used in the definition of the time-variant central frequency, $\omega_c(t)$, and bandwidth parameter, $q(t)$, of the *NSSP* $X(t)$ as

$$\omega_c(t) = \frac{\sigma_{XY}(t)}{\sigma_X^2(t)} \quad (63)$$

$$q(t) = \left(1 - \frac{\sigma_{XY}^2(t)}{\sigma_X^2(t) \sigma_Y^2(t)} \right) \quad (64)$$

The time-variant central frequency and bandwidth parameter are useful in describing the time-variant spectral properties of a real-valued *NSSP* $X(t)$ (Barbato and Conte 2008). The central frequency $\omega_c(t)$ provides the characteristic/predominant frequency of the process at each instant of time. The bandwidth parameter $q(t)$ provides information on the spectral bandwidth of the process at each instant of time. Notice that a *NSSP* can behave as a narrowband and a broadband process at different instants of time. For complex-valued *NSSPs*, the complex-valued central frequency and bandwidth parameter defined in Eqs. 63 and 64 lose the simple physical interpretation available for real-valued *NSSPs*, even though their computation is instrumental to the solution of problems requiring a state-space representation. In addition, the bandwidth parameter $q(t)$ plays an important role in time-variant reliability analysis, since it is an essential ingredient of analytical approximations to the time-variant failure probability for the first-passage reliability problem.

Response Spectral Characterization of Nonclassically Damped MDOF Linear Systems Using Complex Modal Analysis

The state-space formulation of the equations of motion is also advantageous for the computation of the *NGSCs* of response processes of both classically and nonclassically damped linear *MDOF* systems. If only Gaussian input processes are considered, only few spectral characteristics are needed to fully describe the response processes of linear elastic *MDOF* systems, since the response processes are also Gaussian. In particular, if $U_i(t)$ denotes the i -th *DOF* displacement response process of a linear elastic *MDOF* system subjected to Gaussian excitation, the only spectral characteristics required, e.g., for reliability applications, are $\sigma_{U_i}^2(t)$, $\sigma_{\dot{U}_i}^2(t)$, $\sigma_{U_i \dot{U}_i}(t)$ and $\sigma_{U_i \dot{Y}_i}(t)$, where $\dot{Y}_i$ is the first time derivative of the process Y_i defined as

$$\mathcal{Y}(t) = -j \int_{-\infty}^{\infty} \text{sign}(\omega) A_{U_i}(\omega, t) e^{j\omega t} dZ(\omega), \quad i = 1, 2, \dots, n \quad (65)$$

and $A_{U_i}(\omega, t)$ the time-frequency modulating function of the process $U_i(t)$ (Barbato and Conte 2008). The process $\mathcal{Y}(t)$ is the modulation (with the same modulating function $A_{U_i}(\omega, t)$ as process $U_i(t)$) of the Hilbert transform of the stationary process embedded in the process $U_i(t)$. Similarly to the response processes, the following auxiliary state vector process can be defined:

$$\Xi = \begin{bmatrix} \mathcal{Y} \\ \dot{\mathcal{Y}} \end{bmatrix}_{(2n \times 1)} \quad (66)$$

Using complex modal decomposition, the cross-covariance matrices of the response processes and the auxiliary processes can be computed as (Barbato and Vasta 2010)

$$\begin{aligned} E[\mathbf{Z}(t) \mathbf{Z}^T(t)] &= \begin{bmatrix} \mathbf{U}(t) \mathbf{U}^T(t) & \mathbf{U}(t) \dot{\mathbf{U}}^T(t) \\ \dot{\mathbf{U}}(t) \mathbf{U}^T(t) & \dot{\mathbf{U}}(t) \dot{\mathbf{U}}^T(t) \end{bmatrix} \\ &= \tilde{\mathbf{T}}^* E[\mathbf{S}^*(t) \mathbf{S}^T(t)] \tilde{\mathbf{T}}^T \end{aligned} \quad (67)$$

$$\begin{aligned}
 E[\mathbf{Z}(t)\mathbf{\Xi}^T(t)] &= \begin{bmatrix} \mathbf{U}(t)\mathcal{Y}^T(t) & \mathbf{U}(t)\dot{\mathcal{Y}}^T(t) \\ \dot{\mathbf{U}}(t)\mathcal{Y}^T(t) & \dot{\mathbf{U}}(t)\dot{\mathcal{Y}}^T(t) \end{bmatrix} \\
 &= \tilde{\mathbf{T}}^* E[\mathbf{S}^*(t)\mathbf{\Sigma}^T(t)] \tilde{\mathbf{T}}^T
 \end{aligned} \quad (68)$$

where the components of the vector process $\mathbf{\Sigma} = [\Sigma_1(t)\Sigma_2(t) \dots \Sigma_{2n}(t)]^T$ are defined as

$$\begin{aligned}
 \Sigma_i(t) &= -j \int_{-\infty}^{\infty} \text{sign}(\omega) A_{S_i}(\omega, t) e^{j\omega t} dZ(\omega), \\
 i &= 1, 2, \dots, n
 \end{aligned} \quad (69)$$

Eqs. 67 and 68 show that all quantities required for reliability applications can be computed from the following spectral characteristics of complex-valued nonstationary processes ($i, m = 1, 2, \dots, 2n$)

$$\begin{cases} E[S_i^*(t)S_m(t)] = \sigma_{S_i S_m}(t) \\ E[S_i^*(t)\Sigma_m(t)] = \sigma_{S_i \Sigma_m}(t) \end{cases} \quad (70)$$

Response Statistics of MDOF Linear Systems Subjected to Modulated Gaussian-Colored Noise

Time-modulated Gaussian-colored noises constitute an important class of nonstationary dynamic load processes. The expression describing a general nonstationary loading process reduces to

$$F(t) = A_F(t)P(t) \quad (71)$$

where the time-modulating functions $A_F(t)$ are frequency independent, and the process $P(t)$ is a colored noise with PSD function having the following general expression (i.e., rational function):

$$\Phi_P(\omega) = S_0 \sum_{k=1}^N \frac{A_k}{(\omega - \bar{\omega}_k)} \quad (72)$$

In the sequel, it is assumed that the time-modulating functions have the following general expression:

$$A_F(t) = H(t) \sum_{q=1}^M a_q e^{b_q t} \quad (73)$$

Substituting Eq. 73 into Eq. 61 yields ($i = 1, 2, \dots, 2n$)

$$A_{S_i}(\omega, t) = j \sum_{q=1}^M \left\{ a_q e^{b_q t} \left[\frac{e^{-j(\omega - \omega_{1q})t-1}}{\omega - \omega_{1q}} \right] \right\} \quad (74)$$

where $\omega_{1q} = -j\lambda_i$ and $\omega_{1q} = \omega_1 + jb_q$. The spectral characteristics defined in Eq. 70₁ can be computed using Cauchy's residue theorem as ($i, m = 1, 2, \dots, 2n$)

$$\sigma_{S_i S_m}(t) = S_0 \sum_{q,s=1}^M \sum_{k=1}^N a_q a_s A_k \left\{ \left[e^{(b_q + b_s)t} + 1 \right] I_1^{iq, ms, k} - e^{-j\omega_{1q}^* t} I_2^{iq, ms, k} - e^{j\omega_{ms} t} I_3^{iq, ms, k} \right\} \quad (75)$$

in which

$$I_1^{iq, ms, k} = 2\pi j \sum_{r=1}^3 B_r^{iq, ms, k} I(\tilde{\omega}_r) \quad (76)$$

$$I_2^{iq, ms, k} = 2\pi j \sum_{r=1}^3 B_r^{iq, ms, k} e^{j\tilde{\omega}_r t} I(\tilde{\omega}_r) \quad (77)$$

$$I_3^{iq, ms, k} = 2\pi j \sum_{r=1}^3 B_r^{iq, ms, k} e^{-j\tilde{\omega}_r t} I(-\tilde{\omega}_r) \quad (78)$$

where $\tilde{\omega}_1 = \omega_{1q}^*$, $\tilde{\omega}_2 = \omega_{ms}$, $\tilde{\omega}_3 = \bar{\omega}_k$ and

$$\begin{aligned}
 B_r^{iq, ms, k} &= \frac{1}{(\tilde{\omega}_r - \tilde{\omega}_p)(\tilde{\omega}_r - \tilde{\omega}_q)}, \\
 r, p, q &= 1, 2, 3 \quad r \neq p \neq q
 \end{aligned} \quad (79)$$

while

$$I(\omega) = \max \left[\frac{\Im(\omega)}{|\Im(\omega)|}, 0 \right] \quad (80)$$

After extensive algebraic manipulations, the spectral characteristics in Eq. 70₂ are obtained as $(i, m = 1, 2, \dots, 2n)$

$$\sigma_{S_i \Sigma_m}(t) = -jS_0 \sum_{q,s=1}^M \sum_{k=1}^N a_q a_s A_k e^{(b_q+b_s)t} \left\{ \left[e^{j(\omega_{ms}-\omega_{1q}^*)t} + 1 \right] J_1^{iq,ms,k} - e^{-j\omega_{1q}^*t} J_2^{iq,ms,k} - e^{j\omega_{ms}t} J_3^{iq,ms,k} \right\} \quad (81)$$

in which

$$E_1(x) = \int_x^\infty \frac{e^{-u}}{u} du, \quad |\arg(x)| < \pi \quad (85)$$

$$J_1^{iq,ms,k} = -\sum_{r=1}^3 \left\{ B_r^{iq,ms,k} [\log(\tilde{\omega}_r) + \log(-\tilde{\omega}_r)] \right\} \quad (82)$$

A very useful modulating function in earthquake engineering is the one of Shinozuka and Sato, defined as

$$J_2^{iq,ms,k} = 2 \sum_{r=1}^3 B_r^{iq,ms,k} \left\{ e^{\tilde{\omega}_r t} [E_1(j\tilde{\omega}_r t) + j\pi I(\tilde{\omega}_r)] \right\} \quad (83)$$

$$A_F(t) = C [e^{-B_1 t} - e^{-B_2 t}] H(t) \quad (86)$$

where

$$J_3^{iq,ms,k} = 2 \sum_{r=1}^3 B_r^{iq,ms,k} \left\{ e^{-j\tilde{\omega}_r t} [E_1(-j\tilde{\omega}_r t) + j\pi I(-\tilde{\omega}_r)] \right\} \quad (84)$$

$$C = \left[\frac{B_1}{B_2 - B_1} \right] e^{\frac{B_2}{B_2 - B_1} \log\left(\frac{B_2}{B_1}\right)} \quad (87)$$

where $E_1(\cdot)$ denotes the integral exponential function:

and $B_2 > B_1 > 0$. With this position, Eq. 81 reduces to $(i, m = 1, 2, \dots, 2n)$

$$\sigma_{S_i \Sigma_m}(t) = \frac{CS_0}{4\pi} \sum_{q,s=1}^2 \sum_{k=1}^4 (-1)^{k+s+q} e^{(B_q+B_s)t} \left\{ \left[e^{j(\omega_{ms}-\omega_{1q}^*)t} + 1 \right] J_1^{iq,ms,k} - e^{-j\omega_{1q}^*t} J_2^{iq,ms,k} - e^{j\omega_{ms}t} J_3^{iq,ms,k} \right\} \quad (88)$$

where $\omega_{1q} = \omega_1 - jB_q$ ($q = 1, 2$).

Summary

Response analysis of MDOF linear structures showing classical or nonclassical viscous

damping are revised and discussed. Attention is focused on earthquake excitation acting on nonclassically damped linear structures. Spectral characteristics are employed to evaluate the time-variant central frequency and bandwidth parameters, useful for assessing the reliability of earthquake-sensible structures.

Introduction

One of the most significant developments in structural engineering in the past 20 years has

undoubtedly been the emergence of performance-based design as a means of selecting, proportioning, and building structural systems to resist seismic excitations. This methodology is an ideal framework for design due to its flexibility with respect to the selection of performance objectives, the characterization and simulation of both demand and resistance, and the overarching treatment of uncertainty. A great strength of the methodology is that performance objectives may be defined in terms of structural performance, architectural function, socioeconomic considerations, and environmental sustainability. This framework has the attractive feature of providing a metric of performance that can be implemented by a wide variety of infrastructure stakeholders, including architects, building owners, contractors, insurance providers, capital investment proprietors, and public officials. As structural engineers train their focus on broadly defined solutions to the challenges posed by maintaining and improving civilization, performance-based design will increasingly play a central role. This innovative approach to design demands the use of innovative structural systems to achieve the complex and potentially multi-objective performance goals envisioned by the various stakeholders. Given the uncertainty that is unavoidably present in any earthquake-resistant design framework, innovative systems must not only be capable of predictable response to deterministic input but also be sufficiently robust to respond reliably to a broad range of potential input.

Seismic isolation systems are ideally suited for implementation within a performance-based framework because: (a) robust characterizations of their behavior can be made through experimentation, (b) the variance of observed behavior from expected is often low relative to conventional structural elements, and (c) it can be challenging or even impossible to achieve an enhanced performance objective without the use of seismic isolation. Compared to conventional structural system for seismic resistance, isolation provided a unique and reliable means of simultaneously reducing earthquake damage in both

deformation-sensitive and acceleration-sensitive elements.

Performance-based seismic design of structures is currently undergoing significant development in response to consequences experienced in recent earthquakes. Not only has there been substantial loss of human life as a result of damage caused by major earthquakes, the economic toll resulting from direct losses (repair of infrastructure, replacement of damaged contents) and indirect losses (business disruptions, relocation expenses, supply chain interruption) has also been significant. As a result of the significant socioeconomic turmoil due to the occurrence of earthquakes worldwide, innovative systems such as seismic isolation have emerged as a reliable approach to limiting damage and providing post-earthquake functionality and operability.

Principles of Seismic Isolation

Seismic isolation is rooted in the need to control structural response due to harmonic vibrations. This need stems from (a) the discomfort caused to occupants as a result of oscillatory motion of floor-supported equipment and (b) the potential for damage to sensitive equipment caused by vibrations of the supporting structure. The source of such vibrations has traditionally been rotating machinery, ambient traffic conditions, and walker-induced floor vibrations. A common method of reducing the accelerations due to harmonic excitation is to provide a compliant base (either from steel springs or elastomeric pads) that adjusts the natural frequency of the supported equipment such that it is unable to reach resonance under the operating frequency of the excitation. This idea is behind the concept of *transmissibility*, or the ratio of the response amplitude to the input amplitude. For example, in vibration isolation, one can define the transmissibility as the ratio of the peak total acceleration of the equipment to the peak input acceleration of the support. The transmissibility is generally a function of the forcing frequency, the natural frequency of the supporting hardware,

and the amount and type of damping present. Whereas the amplitude and forcing frequency may be a function of the equipment's operating speed and weight, the natural frequency and damping of the supporting hardware may be adjusted to limit the total acceleration due to harmonic excitation.

The reduction of transmissibility is also the goal of seismic isolation. Unlike traditional equipment isolation, however, the excitation is due to ground shaking and therefore cannot be characterized by harmonic input. Ground shaking resulting from a seismic event is stochastic in nature, and this excitation may contain a rich array of frequency content. Data collected from numerous historical seismic events has demonstrated that the predominant frequency of seismic excitation is generally above 1 Hz, and hence systems having a lower natural frequency than this will experience a reduction in transmissibility of acceleration from the ground into the structure. The reduction of natural frequency (or elongation of natural period) provides the so-called "decoupling" of the motion of the structure with that of the ground, as shown in Fig. 1. This reduction in natural frequency has the undesirable consequence of increasing deformation demand under the input excitation. These undesirable deformations can be mitigated to some extent through the addition of damping, typically through a combination of velocity-dependent (termed viscous damping) and deformation-dependent (termed hysteretic damping) energy dissipation mechanisms. As a result, a properly designed isolation system will have the appropriate combination of stiffness and damping such that substantial dynamic decoupling is achieved without detrimental deformation demands in the isolation hardware.

Period elongation is not, however, the only necessary component of seismic isolation. Indeed, if adding flexibility were sufficient to reduce seismic response, then an effective design strategy would be to use the most flexible members possible given the consideration of stability under gravity. An equally important aspect of isolation is the change in fundamental mode

Code-Based Design:

 isolated buildings

shape. The introduction of a layer that is compliant relative to the supported structure introduces a key modification to the free vibration characteristics of the structure. The more similar the fundamental mode shape is to rigid-body behavior, the less mass participation is present in higher modes. Such rigid-body behavior is associated with the relative compliance of the isolation layer. Hence, as the natural period of the isolation system increases relative to the natural period of the supported structure, the participation of higher modes becomes closer to zero and the seismic deformation is concentrated at the isolation layer and not in the superstructure (Fig. 2).

If the isolated structure has total weight W , and the total lateral stiffness of the isolation system is

given by k_b , the isolated natural frequency is defined as

$$\omega_b = \sqrt{\frac{k_b g}{W}} \quad (1)$$

This well-known expression assumes that the mass above the isolation system is rigid, and all lateral deformation takes place in the isolators. This is an approximation and is clearly dependent on the natural frequency of the supported structure, ω_s . However, for reasonable large frequency ratios ω_s/ω_b , this rigid structure assumption is a very good approximation of reality.

Another important parameter for isolated structures is the critical damping ratio of the isolation system, ζ_b . This damping is defined by

the isolation bearings themselves and any supplemental damping devices. The general expression for equivalent damping of an isolation system is given by

$$\zeta_b = \frac{E_d}{4\pi E_s} \quad (2)$$

where E_d is the energy dissipated in one complete cycle of displacement u_0 and E_s is the energy stored at a displacement equal to u_0 . Both parameters of stiffness and damping for specific isolation devices will be further described in the following section.

Preliminary Design of Isolated Structures

The preliminary design of isolated structures generally begins with an assumption of equivalent linear properties for the isolation system and a rigid superstructure. This design approach is sufficient to obtain, for a given level of seismic hazard, design forces and interstory drift demands for the superstructure and peak isolator displacements.

Suppose an isolated structure is being designed at a site characterized by a design-level elastic acceleration response spectrum $A(\omega_n, \zeta)$, where ω_n is the natural frequency and ζ is the viscous damping ratio. The isolation system stiffness k_b is the sum of the individual stiffnesses of each bearing, and the viscous damping ζ_b of the system is computed from Eq. 2. If the total seismic weight supported above the isolation system is W , the isolated natural frequency ω_b is given by Eq. 1. As a result, the design base shear for the isolated structure would simply be computed as

$$V_b = \frac{A(\omega_b, \zeta_b)}{g} W \quad (3)$$

This equation treats the superstructure as a rigid mass single degree-of-freedom system oscillator whose stiffness and damping are entirely defined by the isolation system. This base shear represents the total lateral force delivered to the superstructure given the frequency and damping of the isolation system. This base shear may be

distributed to the superstructure using the first mode shape, and these forces may be used to compute member forces, interstory drifts, etc. While isolated buildings are generally designed to be essentially elastic for design ground motion, the base shear in Eq. 3 may be reduced by an overstrength-based force reduction factor R_Ω . This factor is much less than the force reduction factors R used for ductile fixed-base buildings, since both ductility and overstrength are considered, and conventional buildings are expected to undergo potentially large inelastic deformations in the design earthquake.

The maximum displacement of the isolation system, D_b , is computed from the basic expression for a spring force, $V_b = k_b D_b$. Noting that $k_b = \omega_{n_g}^2 W$ and the relationship between spectral acceleration and displacement is given by $A(\omega_n, \zeta) = \omega_n^2 D(\omega_n, \zeta)$, the maximum isolator displacement is simply

$$D_b = D(\omega_b, \zeta_b)$$

The preliminary design of the individual isolators will be based on the required shear stiffness and damping and the stability of the isolator under the maximum axial load at the maximum displacement D_b . The final design process is more involved and is based on the requirements of the governing building code.

Historical Development of Seismic Isolation

The roots of seismic isolation as a means for protecting structures from earthquakes go back to the latter part of the nineteenth century. While there appeared to be significant interest in creating an innovative seismic protective system, few opportunities were available for practical application. The first documented proposal for a seismic isolation system appears to be in an 1870 US patent filed by Jules Touaillon that describes a double-concave rolling ball bearing (Fenz and Constantinou 2006). Other early proposals include a 1906 US patent by J. Bechtold and a 1909 British patent by J. A. Calantarientis (Buckle

and Mayes (1990), Kelly (1986)). Both patents advocated base isolation through the separation of a building from its foundation, with low-friction material providing the necessary lateral flexibility. Despite the innovative design approaches embodied in these patents, none appear to have seen actual implementation.

The first application of seismic isolation was in 1885 by John Milne, a Professor of Mining Engineering at the University of Tokyo (Naeim and Kelly 1999). Having previously conducted experiments on sliding isolators, Milne designed and constructed a seismic isolation system for a building in Tokyo that incorporated ball bearings and cast iron plates formed in a spherical shape. The first application of seismic isolation using elastomeric bearings was in the Pestalozzi School located in Skopje, Yugoslavia, constructed in 1969 (Kelly 1986). The elastomeric bearings were constructed as blocks of rubber with no intermediate layers of steel reinforcement. This lack of confinement caused substantial vertical deflection under both gravity and lateral loading, resulting in an undesirable combination of horizontal and rocking modes of vibration under earthquake excitation. This early application of rubber in seismic design highlights the development that was underway and identifies the motivation for further research.

Modern seismic isolation originated in the mid-1960s with the New Zealand Department of Scientific and Industrial Research (Skinner et al. 1993). One of the outcomes of this research was the development of the lead rubber bearing, a system that relies on a laminated rubber bearing for horizontal flexibility and a press-fit central lead core to provide energy dissipation. Lead bearings have seen extensive use worldwide, the first application being the William Clayton Building constructed in Wellington, New Zealand, in 1981. Another type of elastomeric bearing is the high-damping rubber bearing, which was first used in the Foothill Communities Law and Justice Center in Rancho Cucamonga, USA, in 1985. The first modern sliding isolation system, the Friction Pendulum System, was developed in 1986 (Zayas et al. 1987) and was used in the retrofit of a wood-framed apartment

building in San Francisco, USA, that was damaged by the 1986 Loma Prieta earthquake.

Since the initial development of reliable, practical isolation devices in the early 1970s, seismic isolation has seen worldwide adoption. Detailed design provisions have been incorporated in several model building codes, and isolated buildings have reportedly been constructed in over 30 countries with the majority found in Japan, China, Russia, Italy, the USA, France, Armenia, Taiwan, and New Zealand (Martelli et al. 2012). Japan in particular has emerged as the worldwide leader in the application and advancement of seismic isolation technology. This was brought on in large part by the 1995 Hyogoken-Nanbu earthquake near Kobe, an event that highlighted the significant seismic risk to buildings and infrastructure in even the most developed countries (Clark et al. 2000).

Seismic Isolation Devices

A critical ingredient of seismic isolation is the introduction of a specially designed stratum between the structure and the foundation that is both horizontally flexible and vertically stiff. A stratum with these properties is generally achieved through a series of manufactured isolation bearings, whose required performance is specified on a set of contract documents, and acceptance is verified through prototype (quality assurance) and production (quality control) testing. Manufactured bearings primarily fall into two categories: elastomeric based or sliding based. Elastomeric-based bearings take advantage of the flexible properties of rubber to achieve isolation, while sliding-based bearings rely on the inherently low stiffness of a structure resting on its foundation with no connection other than friction at the interface. Devices that are designed and manufactured to effectively achieve the goals of seismic isolation possess three general characteristics:

1. High axial stiffness and strength to resist gravity and other vertical loads (both sustained and transient) without excessive deformation that

Code-Based Design: Seismic Isolation of Buildings,
Fig. 3 Typical laminated rubber bearing with cutaway showing internal construction (courtesy of Takenaka Corp., Japan)

would compromise the serviceability of a structure.

2. Sufficiently low horizontal stiffness such that the fundamental frequency of the isolated structure is substantially lower than the predominant frequency content of the expected ground motions, and adequate separation is provided between the natural frequency of the superstructure and that of the isolated structure.
3. An effective mechanism for energy dissipation to mitigate excessive lateral deformations which might cause instability of the isolation devices and connected structural elements due to combined horizontal and vertical forces.

Categories of devices currently manufactured to exhibit these characteristics are discussed in this section.

Elastomeric Isolation Bearings

Elastomeric isolation bearings are devices that make use of the flexibility of natural or synthetic rubber compounds to achieve the characteristics necessary for an effective isolation system. Such bearings have been widely used in bridge applications since the early part of the twentieth century to accommodate translational and rotational movement resulting from thermal expansion while supporting the weight of the deck (Fig. 3).

Low-Damping Rubber (LDR) Bearings

The most fundamental elastomeric isolation bearing is the low-damping rubber (LDR) bearing. This device consists of alternating layers of rubber and steel, providing the device with both high axial stiffness and low shear stiffness. The effective shear modulus of the rubber compound, G , is generally a function of the imposed shear strain γ . However, for natural rubber, there is a weak dependence of shear modulus on shear strain and may be assumed constant over a typical range of shear strain assumed in the design of isolation bearings subject to earthquakes. To derive the stiffness of an LDR bearing, first consider a single rubber layer having bonded area A_b and thickness t_r . Given an imposed shear stress τ , the total horizontal shear force acting on the layer is given as $V = \tau A_b$. From Hooke's law, the shear stress is $\tau = G\gamma$, so the total shear is $V = GA_b\gamma$. The shear displacement is simply $u = t_r\gamma$, giving shear force in terms of shear displacement

$$V = \frac{GA_b}{t_r} u \quad (4)$$

The layer stiffness is therefore GA_b/t_r . Since the total horizontal flexibility of the bearing is the sum of the individual layer flexibilities, considering a bearing with n rubber layers, the horizontal stiffness of an NR bearing is given by

$$k_b = \frac{GA_b}{T_r} \quad (5)$$

where the total rubber thickness is $T_r = nt_r$. Given an isolation system consisting of multiple isolators each having effective stiffness $k_{b,j}$, the natural period of the isolated building would be computed as

$$T_b = 2\pi \sqrt{\frac{W}{g \sum_j k_{b,j}}} \quad (6)$$

where W is the total weight of the supported structure. The vertical stiffness of an LDR bearing is given by

Code-Based Design: Seismic Isolation of Buildings, Fig. 4 Hysteresis for a low-damping rubber bearing (a) $\gamma = 75\%$; (b) $\gamma = 175\%$ (Constantinou et al. 2007)

$$k_v = \frac{E_c A_b}{T_r} \quad (7)$$

where E_c is the compression modulus of the rubber layer. This compression modulus is a function of the *shape factor* S , defined as the ratio of the bonded area to the area free to bulge. For circular bearings with bonded diameter D_b , the shape factor is computed as $S = D_b/4t_r$. For a rectangular bearing having dimensions $a \times b$, the shape factor is computed as

$$S = \frac{ab}{2t_r(a+b)} \quad (8)$$

If the shape factor is sufficiently low, for circular bearings, $E_c = 6GS^2$, and for square bearings, $E_c = 6.73GS^2$ (Naeim and Kelly 1999). Typical shape factors for modern elastomeric bearings range from 10 to 30 and result in extremely high compressive stiffness. At these high shape factors, the bulk modulus K of the rubber becomes important. An expression for the compressive modulus incorporating the effect of the bulk modulus is given as

$$E_c = \frac{6GS^2K}{6GS^2 + K} \quad (9)$$

Elastomeric bearings in tension behave much differently than in compression. Whereas laminated rubber bearings can resist large compressive stress with no damage to the rubber matrix, tension stresses cause cavitation and significant loss of axial stiffness. For this reason, the design of isolated buildings is based in part of distributed overturning forces at the isolation layer such that uplift forces are minimized (Fig. 4).

High-Damping Rubber (HDR) Bearings

A class of elastomeric bearings that has seen wide implementation is high-damping rubber (HDR). These bearings are similar in construction to LDR bearings; however, the natural or synthetic rubber is specially compounded with carbon black, oils, resins, and other fillers that increase the inherent damping characteristics of the rubber (Clark and Kelly 1994). HDR bearings are characterized by effective shear modulus G_{eff} and equivalent viscous damping ζ_{eq} that is a function primarily of shear strain but also exhibits dependence on strain rate, strain history, and aging (Morgan et al. 2001). Several highly sophisticated models have been developed that are capable of predicting the behavior of HDR bearings over a wide range of response amplitudes (e.g., Yamamoto et al. (2012), among others). Such models rely on a combination of nonlinear elastic

Code-Based Design: Seismic Isolation of Buildings, Fig. 5 Hysteresis of full-scale HDR bearings indicating (a) substantial strain crystallization and (b) low strain crystallization (Yamamoto et al. (2012))

springs, variable yield force plasticity elements, and variable stiffness springs. These models are then calibrated to experimental data.

A unique feature of HDR bearings is a phenomenon known as large strain crystallization, which causes an evident increase in stiffness above 120–150 % shear strain. Hysteresis loops for full-scale HDR bearings with and without significant large strain crystallization are shown in Fig. 5.

Another unique property of HDR bearing is the strain history dependence of both effective stiffness and equivalent viscous damping. Experimental programs (e.g., Morgan et al. 2001) have demonstrated the variability of measured stiffness and damping depending on the nature of the input loading. For example, the effective stiffness measured at 100 % shear strain (a common design parameter) could be markedly different for a test in which the bearing first experienced a shear strain of 250 % compared to a test that only includes strain amplitudes of 100 %. Another related effect is the increased stiffness measured in the first cycle of displacement compared to the stiffness in subsequent cycles. This effect is known as scragging and appears to be a persistent feature of HDR compounds. A hysteresis loop of an HDR bearing showing the effects of scragging is presented in Fig. 6.

Strain rate is also an important consideration in the modeling of HDR bearings. Testing of

Code-Based Design: Seismic Isolation of Buildings, Fig. 6 Hysteresis loop of reduced-scale HDR bearing showing scragging effect

HDR bearings at various frequencies has indicated that the measured stiffness and damping of the HDR compound is a function of both shear strain amplitude and velocity. As a result, any suitable model for an HDR bearing must include both hysteretic and viscous behavior to properly account for the likely energy dissipation characteristics over a broad range of seismic excitations. Further information on simple combined models capable of capturing this behavior is developed in Naeim and Kelly (1999).

Lead Rubber (LR) Bearings

The lead rubber (LR) bearing consists of a low-damping natural rubber bearing, as described previously, with a press-fit central lead core. A cutaway section of a typical LR bearing is shown in Fig. 7. The bearing has linear behavior identical to the LRB bearing described above, and the stiffness is described by Eq. 5. The lead plug behaves as an elasto-perfectly plastic hysteretic element with a yield shear force $q_d = \tau_y A_{pb}$ where τ_y is the yield stress of lead and A_{pb} is the area of the lead core. Lead is an attractive material for the lead core since it is malleable, has a low yield stress that is stable for high levels of purity, and is readily available. A bilinear force–deformation loop for an LR bearing is shown in Fig. 8.

Most isolation devices are characterized by effective stiffness, k_{eff} , and equivalent viscous damping ζ_{eq} . For LR bearings, the effective stiffness assuming the above bilinear hysteretic model is computed as

$$k_{eff} = \frac{q_d}{u} + k_b \quad (10)$$

The effective period of a system of LR bearings is computed as

Code-Based Design: Seismic Isolation of Buildings, Fig. 7 Typical lead rubber bearing with cutaway showing internal construction (courtesy of Takenaka Corp., Japan)

$$T_b = 2\pi \sqrt{\frac{W}{g \sum_j k_{eff,j}}} \quad (11)$$

where $k_{eff,j}$ is the effective stiffness of the j th isolator. The equivalent viscous damping of a single isolator is given as

$$\zeta_{eq} = \frac{1}{4\pi} \frac{E_d}{E_s} \quad (12)$$

where the energy dissipated per cycle $E_d = 4q_d(u - u_y)$ and the elastic energy stored $E_s = \frac{1}{2}k_{eff}u^2$. Substituting these expressions into Eq. 12 gives an expression for ζ_{eq} that is a function of bearing properties q_d , u_y , k_b , and the displacement u :

$$\zeta_{eq} = \frac{2q_d(u - u_y)}{\pi u(q_d + k_b u)} \quad (13)$$

The equivalent damping of a system of LR bearings is computed as

$$\zeta_{eq} = \frac{\sum_j \zeta_{eq,j} k_{eff,j}}{\sum_j k_{eff,j}} \quad (14)$$

where $\zeta_{eq,j}$ is the effective stiffness of the j th isolator. In other words, the system equivalent

Code-Based Design: Seismic Isolation of Buildings, Fig. 8 Bilinear force–displacement relationship for LR bearings

damping is the weighted arithmetic mean of the individual damping values where the individual stiffnesses are the weighting factors.

Sliding Isolation Bearings

Flat Sliders

In cases where an elastomeric bearing supports low axial loads, it may be either impractical or unnecessarily costly to resist these axial loads using one of the bearings previously described. Instead, it is often preferable to install a flat sliding surface that allows the column to simply move with the isolation level diaphragm. These bearings typically have low friction coefficients and are inexpensive relative to the isolation bearings. One type of flat slider is the cross linear bearing, shown in Fig. 9, which provides the features of a typical flat slider with the addition of tension-resistant behavior. These have been implemented in high-rise buildings in Japan to resist the uplift forces below columns due to overturning effects.

Code-Based Design: Seismic Isolation of Buildings, Fig. 9 Cross linear bearing (courtesy of THK Co., Ltd.)

Single-Pendulum (SP) Bearings

The single-pendulum bearing is the original Friction Pendulum™ System described by Zayas et al. (1987) and represents the first manufactured sliding bearing to make use of the pendulum concept. This bearing consists of an articulated slider resting on a concave spherical surface. The slider is coated with a woven PTFE (polytetrafluoroethylene) composite liner, and the spherical surface is coated with a polished stainless steel overlay. A picture showing an SP bearing and a cross section is shown in Fig. 10, indicating the above-described components.

Although there is an abundance of published work on the cyclic behavior of SP bearings (e.g., Zayas et al. 1990 and Mosqueda et al. 2004, among others), it is useful to recapitulate the essential aspects of their behavior. To develop a mathematical model of the force–displacement relationship of an SP bearing, the geometry of the device must be fully understood.

First, we can write the equilibrium equations of the bearing in its displaced condition (as seen above in Fig. 11), summing forces along the horizontal and vertical axes and obtaining

$$\begin{pmatrix} V \\ W \end{pmatrix} = \begin{bmatrix} \cos \varphi & \sin \varphi \\ -\sin \varphi & \cos \varphi \end{bmatrix} \begin{pmatrix} f_t \\ f_n \end{pmatrix} \quad (15)$$

From geometry, it is clear that $\sin \varphi = u/R$ and $\cos \varphi = \sqrt{R^2 - u^2}/R$; hence, Eq. 15 can be written as

$$\begin{pmatrix} V \\ W \end{pmatrix} = \frac{1}{R} \begin{bmatrix} \sqrt{R^2 - u^2} & u \\ -u & \sqrt{R^2 - u^2} \end{bmatrix} \begin{pmatrix} f_t \\ f_n \end{pmatrix} \quad (16)$$

Code-Based Design: Seismic Isolation of Buildings, Fig. 10 Photo (left) and section (right) of a typical SP bearing

Code-Based Design: Seismic Isolation of Buildings,
Fig. 11 Equilibrium of slider in displaced configuration

Assuming the tangential traction f_t is related to the normal traction f_n through Coulomb friction by the equation $f_t = \mu f_n$ (where μ is the coefficient of friction) and defining a normalized shear force $\tilde{V} = V/W$, Eq. 16 reduces to

$$\tilde{V} = \frac{\mu\sqrt{R^2 - u^2} + u}{\sqrt{R^2 - u^2} - \mu u} \quad (17)$$

Equation 17 returns a normalized shear force in the bearing given an imposed displacement u . While in some cases it may be important to consider the large displacement formulation of the normalized restoring force, a common simplifying assumption here is useful. For virtually all SP bearings, the effective radius of curvature R is much greater than the maximum expected displacement u . The consequence of this assumption can be seen by expanding $g(u) = \sqrt{R^2 - u^2}$ in a Taylor series about the point $u = 0$. Carrying out this expansion yields the series

$$\sqrt{R^2 - u^2} = R - \frac{1}{2}R\left(\frac{u}{R}\right)^2 - \frac{1}{8}R\left(\frac{u}{R}\right)^4 - \dots \quad (18)$$

From this series, it is clear that for $R \gg u$, $\sqrt{R^2 - u^2} \approx R$. Substituting this approximation

Code-Based Design: Seismic Isolation of Buildings,
Fig. 12 Idealized hysteresis loop of single-concave SP bearing based on Eq. 19

into Eq. 17 and simplifying, the actual restoring force is

$$V = \mu W \text{sgn}(\dot{u}) + \frac{W}{R} u \quad (19)$$

This is the well-known force-deformation relation for a single-concave SP bearing at a particular sliding displacement u and velocity $\dot{u}$. The function $\text{sgn}(\cdot)$ is the *signum* function and returns 1 (or -1) if the argument is positive (or negative). The inclusion of the *signum* function is necessary since the direction of the friction force always opposes that of the sliding velocity. A normalized force-deformation plot of an SP bearing under one complete cycle of loading, based on Eq. 19, is shown in Fig. 12.

An implication of Eq. 19 is that the frequency characteristics of a rigid structure isolated on SP bearings are independent of its mass. This can be seen by writing the equation of motion for an undamped single degree-of-freedom oscillator with an SP bearing as the restoring force (where m is the supported mass; hence, $W = mg$). Neglecting friction, the equation of motion and the resulting natural period is given by

$$m\ddot{u} + \frac{mg}{R}u = 0 \quad \Rightarrow \quad T_b = 2\pi\sqrt{\frac{R}{g}} \quad (20)$$

Most isolation devices are characterized by effective stiffness, k_{eff} , and equivalent viscous

damping ζ_{eq} . For SP bearings it is appropriate to normalize effective stiffness by the supported weight W , or

$$\tilde{k}_{eff} = \frac{\tilde{V}}{u} = \frac{\mu}{u} + \frac{1}{R} \quad (21)$$

Note that $\tilde{k}_{eff}$ has units of $[1/L]$, and the actual effective stiffness is simply $k_{eff} = \tilde{k}_{eff}W$. Similarly, the equivalent viscous damping is given as

$$\zeta_{eq} = \frac{1}{4\pi} \frac{E_D}{E_S} \quad (22)$$

where the energy dissipated per cycle $E_D = 4\mu Wu$ and the elastic energy stored $E_S = \frac{1}{2}k_{eff}u^2$. Substituting these expressions into Eq. 22 gives an expression for ζ_{eq} that is a function of bearing properties R , μ and the displacement u :

$$\zeta_{eq} = \frac{2R\mu}{\pi(R\mu + u)} \quad (23)$$

Note that the equivalent damping is independent of the weight supported by the SP bearing. Another way to express the equivalent damping is by recognizing that the friction shear force at slip is $V_f = \mu W$, and the shear force in the bearing is $V_b = k_{eff}u$. In terms of these physically meaningful forces, the equivalent damping is given as

$$\zeta_{eq} = \frac{2}{\pi} \frac{V_f}{V_b} \quad (24)$$

For an SP system with friction coefficient of 0.06 and a peak base shear coefficient of 0.25, the equivalent damping can easily be computed as

$$\zeta_{eq} = \frac{2}{\pi} \frac{0.06}{0.25} = 0.15 \quad (25)$$

Multi-pendulum Bearings

Recent developments in the design and manufacturing of FP bearings have centered around the use of multiple pendulum mechanisms. Whereas the single-concave FP bearing has two key parameters that characterize cyclic

behavior (R and μ), a multistage FP bearing has greater design flexibility because the pendulum lengths and friction coefficients are specific for each independent pendulum mechanism. The triple-pendulum (TP) bearing introduced by EPS, Inc. consists of four concave surfaces and three independent pendulum mechanisms. The outer slider consists of concave surfaces on either side of a cylindrical inner slider with a low-friction interface on both ends. This forms one pendulum mechanism and defines the properties of the isolation system under low levels of excitation. The outer slider also consists of sliding interfaces between top and bottom outer sliders and the major spherical surfaces of the bearing. The bottom sliding surface is in contact with a spherical surface of a particular radius of curvature, forming the second pendulum mechanism. This mechanism defines the primary properties of the isolation system under moderate levels of excitation. The upper sliding surface is in contact with another spherical surface of a particular radius of curvature, forming the third pendulum mechanism. The friction coefficient of this third sliding interface is sufficiently large to prevent sliding until an extreme level of excitation occurs. For this type of bearing, shown in Figs. 13 and 14, the parameters characterizing the cyclic behavior are (R_1, μ_1) for the inner concave sliding interfaces, (R_2, μ_2) for the bottom outer surface, and (R_3, μ_3) for the top outer surface. The slider heights define the kinematic relations for the positions of each sliding surface. The behavior of the triple-pendulum bearing has been described by Morgan (2007) and Fenz and Constantinou (2008a, b).

Given the geometry and properties of the TP bearing, the force–displacement relationship for the element can be derived by taking equilibrium in the deformed configuration. The TP bearing cannot, however, be treated simply as a series of three single-pendulum elements, as this would ignore the relative rotation of the inner slider relative to the outer concave surfaces. A complete derivation of the monotonic force–deformation relation for the TP bearings has been presented by Morgan (2007) and Fenz and Constantinou (2008a, b). This relation is depicted in Fig. 15,

**Code-Based Design:

Buildings,**

Fig. 13 Triple-pendulum
(TP) bearing showing
internal components
(courtesy of EPS, Inc.)

Code-Based Design: Seismic Isolation of Buildings, Fig. 14 Exploded cross section of triple-pendulum bearing showing geometric and friction parameters

showing each of the five stages of unidirectional sliding. Here the effective pendulum lengths are defined as $L_j = R_j - h_j$ where R_j is the radius of the j th sliding surface and h_j is the height of the j th slider, as shown in Fig. 14.

The main feature of the TP bearing is that stiffness and damping properties evolve with increasing displacement. Moreover, this evolution of stiffness and damping can be controlled by varying the radii and friction coefficients of

each sliding surface. This results in a wide variety of realizable hysteretic relations, and proper optimization of the parameters results in a TP bearing that is “tuned” for a particular seismic hazard and performance objective (Fig. 16).

Energy Dissipation Devices

An important consideration in the design of isolated structures is the energy dissipation of the isolation system. While LR, HDR, and FP

Code-Based Design: Seismic Isolation of Buildings, Fig. 15 Monotonic force–deformation relation for triple-pendulum (TP) bearing (Morgan 2007)

**Code-Based Design:
Seismic Isolation of
Buildings,**

Fig. 16 Measured cyclic behavior for reduced-scale triple-pendulum (TP) bearing (Fenz and Constantinou 2008b)

bearings have internal damping mechanisms, the seismicity at a site may be significant and the expected deformation demands may be excessive given the stability requirements of the bearings. In such cases, supplemental energy dissipation devices may be specified to control the expected deformations. These devices can be categorized as either viscous dampers or hysteretic dampers. The details of each are discussed herein.

Fluid Viscous Dampers

One class of supplementary energy dissipation devices is fluid viscous dampers (FVD). These dampers function as a dashpot, dissipating energy by forcing a viscous fluid through a set of orifices in a piston head, which results in heat generation. These dampers are precision devices, manufactured to achieve a target damping coefficient and velocity dependence.

Force–displacement
relationship for linear
viscous damper ($\alpha = 1$)
and nonlinear viscous
damper ($\alpha = 0.3$)

The force output F_d of a viscous damper is given by

$$F_d = c_d |\dot{u}|^\alpha \text{sgn}(\dot{u}) \quad (26)$$

where c_d is the damping coefficient and α is the velocity exponent. In the case than $\alpha = 1.0$, the damper is classified as a linear viscous damper. Otherwise, the damper is classified as nonlinear. Linear dampers are characterized by an elliptical force–displacement loop for harmonic motion, whereas nonlinear dampers have more rectangular loops with rounded corners (see Fig. 17). In both cases, the force output of the damper at maximum displacement (and hence zero velocity) is equal to zero. A major advantage of viscous

damper is the phase lag in force output of the isolation devices and the damping devices. Since isolation bearings are deformation dependent, the peak force output occurs at peak displacement, and zero force output occurs at zero displacement. This is in contrast to viscous dampers, in which the peak force output occurs at zero displacement (or peak velocity), and zero force output occurs at peak displacement (or zero velocity). For moderate levels of damping, isolator displacements are reduced without an increase in total building base shear (Fig. 18).

The design of isolation systems is based on the natural frequency of the isolation system, ω_b , and the equivalent viscous damping, ζ_b . For some

Code-Based Design: Seismic Isolation of Buildings, Fig. 19 Metallic yielding dampers for use at isolation plane

harmonic displacement with amplitude u_0 and forcing frequency $\bar{\omega}$, the energy dissipation for one cycle, E_d , is given by (Soong and Constantinou 1994)

$$E_d = \lambda(\alpha) C_d u_0^{1+\alpha} \bar{\omega}^\alpha \quad (27)$$

where $\lambda(\alpha)$ is defined in terms of the gamma function and is given by

$$\lambda(\alpha) = 4(2^\alpha) \frac{\Gamma^2(1 + \alpha/2)}{\Gamma(2 + \alpha)}, \quad (28)$$

$$\Gamma(x) = \int_0^\infty u^{x-1} e^{-u} du$$

It is useful to define a weight-normalized damping coefficient, $\bar{c}_d = c_d/mg$, where m is the total supported mass of the isolation system. From the equation for equivalent viscous damping, the equivalent damping ζ_{eq} for an isolation system with viscous dampers is given by

$$\zeta_{eq} = \frac{\lambda(\alpha)}{2\pi} \bar{c}_d u_0^{\alpha-1} \omega_b^{\alpha-2} g \quad (29)$$

Two special cases of viscous dampers are linear viscous ($\alpha = 1.0$) and pure friction ($\alpha = 0$). For linear viscous dampers, the equivalent damping is given by the simple and well-known expression

$$\zeta_{eq} = \frac{\bar{c}_d g}{2\omega_b} \quad (30)$$

For pure friction dampers, the equivalent damping is given by

$$\zeta_{eq} = \frac{2\bar{c}_d g}{\pi u_0 \omega_b^2} \quad (31)$$

For general nonlinear viscous dampers, a convenient and highly accurate approximation is given by $2\pi/\lambda(\alpha) \approx 0.4\alpha + 1.6$ (Morgan and Mahin 2011). This results in a simplified expression for the equivalent damping

$$\zeta_{eq} \approx \frac{\bar{c}_d u_0^{\alpha-1} \omega_b^{\alpha-2} g}{0.4\alpha + 1.6} \quad (32)$$

Hysteretic Dampers

Devices that dissipate energy through metallic yielding or friction are classified as hysteretic dampers. These dampers are characterized by an elastic stiffness k_e and a yield force f_y and are generally considered to behave elasto-perfectly plastic (much like the lead plug in the LR bearing). Two hysteretic dampers that have been implemented in Japan are shown in Fig. 19. Unlike viscous dampers, hysteretic dampers are displacement dependent, and the force output is in phase with the forces in the isolation system. As a result, the addition of hysteretic dampers, while reducing the peak displacement of the isolators, may introduce substantially higher forces in the superstructure and foundations.

The presence of hysteretic dampers increases both the effective stiffness and equivalent damping of the isolation system. Suppose an isolation system without dampers has effective stiffness k_{eff} and equivalent damping ζ_{eq} . Furthermore, a group of hysteretic dampers are to be added whose aggregate elastic stiffness and yield force are given by k_e and f_y , respectively. For these dampers subjected to a lateral displacement u , the energy dissipated per cycle $E'_d = 4f_y(u - u_y)$, where $u_y = f_y/k_e$. The effective stiffness of the dampers is $k'_{eff} = f_y/u$. From Eq. 2, the added equivalent damping is

$$\zeta'_{eq} = \frac{2}{\pi} \frac{(u - u_y)}{u} \quad (33)$$

Notably, for small yield displacement u_y , the equivalent damping is a constant $\zeta'_{eq} = 2/\pi \approx 0.64$ and is independent of the damper yield force f_y or isolator lateral displacement u .

The total effective stiffness of the combined isolator/damper system is

$$k_{eff,t} = k_{eff} + k'_{eff} \quad (34)$$

From Eq. 14, the total equivalent damping for the combined isolator/damper system is

$$\zeta_{eq,t} = \frac{\zeta_{eq}k_{eff} + \zeta'_{eq}k'_{eff}}{k_{eff} + k'_{eff}} \quad (35)$$

Design Provisions for Isolated Buildings

Throughout the world, there are a number of published design provisions devoted to the design of seismic isolated structures. The principal goal of these provisions is to ensure that isolated structures maintain an acceptable level of safety to the public in the event of an earthquake. The discussion herein focuses on ASCE 7–10, which contains provisions governing design of seismic isolated buildings in the USA.

The commentary to the 2003 National Earthquake Hazards Reduction Program (NEHRP) Provisions (BSSC 2003) states that isolated

structures designed to those provisions should be able to:

1. Resist minor and moderate levels of earthquake ground motion without damage to structural elements, nonstructural components, or building contents
2. Resist major levels of earthquake ground motion without failure of the isolation system, without significant damage to structural elements and nonstructural components, and without major disruption of the function of the facility

This is an implicit two-stage performance objective that seeks to minimize damage to the building for moderate levels of ground shaking while preventing major losses in the event of a design earthquake (DE) event. The commentary goes on to state that “the above performance objectives for isolated structures considerably exceed the performance anticipated for fixed-base structures during moderate and major earthquakes.” It is crucial to distinguish the performance expectations for conventional and isolated building designed to the same ASCE 7–10 provisions, as conventional buildings are only designed to limit the likelihood of collapse in the event of a maximum-considered earthquake (MCE).

Isolation systems which are deemed acceptable by the provisions of ASCE 7–10 have the following general characteristics:

1. Maintain stability when subjected to design displacements
2. Provide increasing lateral resistance with increasing displacement
3. Suffer no strength or stiffness degradation under repeated cyclic loading
4. Have quantifiable force–deflection and damping characteristics

Analysis Methods

The analysis of isolated buildings is generally conducted by one of three possible methods: equivalent lateral force (static) analysis, response spectrum analysis, and response history analysis.

Each analysis method is capable of representing the peak internal forces and deformations in both the superstructure and isolation system given a design level of seismic intensity and may be used to select and proportion both structural elements and isolation devices.

Equivalent Lateral Force Procedure

The simplest analysis procedure is the equivalent lateral force (ELF) procedure, which is analogous to the static design procedures for conventional structures. In this procedure, the 5 % damped design spectral acceleration for a site at a period of 1 s, S_{D1} , represents the design input.

$$D_D = \frac{gS_{D1}T_D}{4\pi^2B_D} \quad (36)$$

where T_D is the DE effective period, g is the gravitational constant, and B_D is a factor to account for the equivalent damping of the isolation system. While B_D is based on tabulated value, this can be approximated by the equation $B_D = 2.4\zeta_{eq}^{0.3}$ where ζ_{eq} is the equivalent damping computed for the isolation system. The DE effective period is computed as

$$T_D = 2\pi\sqrt{\frac{W}{k_{D\min}g}} \quad (37)$$

where W is the total supported weight of the building and $k_{D\min}$ is the lower-bound effective stiffness of the isolation system at a displacement D_D . The base shear of the superstructure is computed as

$$V_s = \frac{k_{D\max}D_D}{R_I} \quad (38)$$

where $k_{D\min}$ is the upper-bound effective stiffness of the isolation system at a displacement D_D and R_I is the response modification factor for the superstructure and is based on 3/8 times the value of R for a conventional structure with the same lateral system (not to exceed $R_I = 2.0$). This R_I factor is substantially smaller than the R factor for conventional structures because of the enhanced

performance objectives and the resulting need to maintain essentially elastic behavior in the structure. This base shear is also subjected to several lower-bound limits to prevent yielding of the building prior to activation of the isolation system and excessive movement under the design wind loads.

Once the base shear V_s has been computed, the lateral forces on the building are distributed vertically using the equation

$$F_x = V_s \frac{w_x h_x}{\sum_{i=1}^n w_i h_i} \quad (39)$$

where F_x is the lateral force at story x , w_i is the story weight at the i^{th} floor, and h_i is the height above the grade to the i^{th} floor.

The isolation system must be designed such that the elements of this system remain stable given an MCE event. Given a 5 % damped MCE spectral acceleration for a site at a period of 1 s of S_{M1} , the displacement of the isolators is computed as

$$D_M = \frac{gS_{M1}T_M}{4\pi^2B_M} \quad (40)$$

where T_M is the MCE effective period and B_M is similar to B_D in Eq. 36, computed at the displacement D_M . The MCE effective period is computed as

$$T_M = 2\pi\sqrt{\frac{W}{k_{M\min}g}} \quad (41)$$

where $k_{D\min}$ is the lower-bound effective stiffness of the isolation system at a displacement D_M . The isolation system must be designed for this displacement D_M plus the additional effects of both actual and accidental torsion.

The ELF procedure is permitted for analysis of isolated buildings provided the following restrictions are met:

1. Building is vertically regular.
2. MCE spectral acceleration $S_{M1} < 0.6$ g.
3. $T_M \leq 3.0$ sec.

4. Soil type A, B, C, or D.
5. Height not greater than four stories or 20 m (65 ft).
6. $T_D/T_s > 3.0$.
7. Positive incremental stiffness of isolation system.
8. $T_D > T_{0.2D}/3$.
9. Isolation system does not limit MCE displacement to less than the total maximum displacement.

Response Spectrum Procedure

Where the ELF procedure is not permitted, it is often permissible to use the response spectrum procedure for design. In this procedure internal forces and deformations are computed using response spectrum analysis, as described by Chopra (2007), among others. In this procedure, the natural frequencies and modes of vibrations of the isolated building are computed in the usual way, and demands are calculated through linear combination of these modes weighted by their spectral ordinates at each natural frequency. The results obtained from response spectrum analysis are not permitted to exceed those computed from the ELF procedure.

This procedure may be used unless the rate-dependence, load history-dependence, or deformation-hardening characteristics of the isolation system necessitate explicit consideration of their nonlinear and/or velocity-dependent force–deflection properties.

Response History Procedure

In any case, an isolated building may be analyzed using the response history procedure. In this procedure, the internal forces and deformations of the structure and isolation system are computed from an ensemble of ground motion acceleration records. Where seven or more records are considered in the analysis, the demands may be based on the ensemble average; otherwise, the demands must be based on the ensemble maximum. No less than three records may be used in the analysis.

The model of the building and isolation system is developed to incorporate any potential nonlinear behavior. Whereas the building is

generally designed to be essential, most isolation devices are characterized by some combination of nonlinear and velocity-sensitive behavior. These behaviors must be included in the response history model.

Limits of Dynamic Results

The demands computed from either the response spectrum or response history procedures may not exceed those from the ELF procedure by more than specified amounts. Figure 20 contains a reproduction of a table from the commentary to ASCE 7–10 that lists the limits imposed on dynamic procedures for a variety of force and deformation demands.

Testing Requirements

ASCE 7–10 requires that the stiffness and damping values for the isolation system used in analysis and design are based on physical tests of the isolation devices. Such testing can be divided into either prototype tests or production tests. Prototype tests are conducted on two identical units or each isolator type in order to establish adequate performance under the entire range of possible demands to which the isolators may be subjected. These tests are prescribed to characterize the behavior of each device under wind loads and both the DE and MCE levels of seismic intensity. These tests must consider maximum and minimum expected axial loads considering both gravity and seismic effects. The prototype test program prescribed by ASCE 7–10 is as follows:

1. Twenty fully reversed cycles of loading at a lateral force corresponding to the wind design force
2. Three fully reversed cycles of loading at each of the following increments of the total design displacement: $0.25D_D$, $0.5D_D$, $1.0D_D$, and $1.0D_M$
3. Three fully reversed cycles of loading at the total maximum displacement, $1.0D_{TM}$
4. $30 S_{D1}/S_{DS}B_D$, but not less than 10, fully reversed cycles of loading at 1.0 times the total design displacement D_{TD}

Table C13.2-2 Lower-Bound Limits on Dynamic Procedures Specified in Relation to ELF Procedure Requirements

Design Parameter	ELF Procedure	Dynamic Procedure	
		Response Spectrum	Response History
Design displacement – D_D	$D_D = (g/4\pi^2)(S_{D1}T_D/B_D)$	–	–
Total design displacement – D_T	$D_T \geq 1.1D$	$\geq 0.9D_T$	$\geq 0.9D_T$
Maximum displacement – D_M	$D_M = (g/4\pi^2)(S_{M1}T_M/B_M)$	–	–
Total maximum displacement – D_{TM}	$D_{TM} \geq 1.1D_M$	$\geq 0.8D_{TM}$	$\geq 0.8D_{TM}$
Design shear – V_b (at or below the isolation system)	$V_b = k_{Dmax}D_D$	$\geq 0.9V_b$	$\geq 0.9V_b$
Design shear – V_s ("regular" superstructure)	$V_s = k_{Dmax}D_D/R_I$	$\geq 0.8V_s$	$\geq 0.6V_s$
Design shear – V_s ("irregular" superstructure)	$V_s = k_{Dmax}D_D R_I$	$\geq 1.0V_s$	$\geq 0.8V_s$
Drift (calculated using R_I for C_d)	$0.015h_{sx}$	$0.015h_{sx}$	$0.020h_{sx}$

Code-Based Design: Seismic Isolation of Buildings, Fig. 20 Reproduction of Table C13.2–2 in commentary to ASCE 7–10 (ASCE 2010)

**Code-Based Design:
Seismic Isolation of
Buildings,**

Fig. 21 Prototype test of a triple-pendulum (TP) bearing, conducted by EPS, Inc.

Acceptance criteria for these tests are developed by the engineer of records and are generally focused on meeting a specified range of stiffness and damping values for the DE tests and maintaining stability in the MCE tests. Figure 21 shows a triple-pendulum (TP) bearing during prototype testing.

Production testing, while not explicitly prescribed by ASCE 7–10, is specified on most

projects. These tests are meant to ensure that fabricated isolators meet the established range of stiffness and damping properties prior to installation. A common production test program requires three fully reversed cycles at displacement amplitude D_D , considering the average gravity loads acting on the isolator type. These tests are often conducted on each isolator prior to installation but could be

limited to some sample subset at the discretion of the engineer and owner.

Design Review Requirements

ASCE 7–05 mandates a design review of the isolation system and related testing program by an independent panel composed of qualified individuals with experience in earthquake engineering principles and analysis and design of seismic isolation systems. This process typically includes a review of the following: the seismic hazard at the site and any ground motions that may be developed, the preliminary design of the isolation system, the observation of the prototype and production testing programs, and the final analysis and design of the entire structural system. The design review is often an interactive process where comments and suggestions are provided to the design team, who can then incorporate these in early schematic phases. This continuous interaction largely prevents significant divergence in the design approach adopted by the design team and the preferred approach advocated by the review panel. A healthy design review process is generally one that promotes a combination of sound engineering judgment and technically accurate analysis methods. As seismic isolated buildings are expected to achieve enhanced performance in a design earthquake, the review panel's principal role is to give the owner their independent assessment of the expected performance of the building and whether it meets the building code's intended performance objectives.

Introduction

The effectiveness and efficiency of community recovery following a disaster is shaped not just by nature and scale of the physical impacts of the event but also on how the social environment supports the complex and protracted processes of recovery (Olshansky et al. 2006; Paton et al. 2014). Recent research following a number of disasters has highlighted the complex nature of community recovery and the

importance of not only strong local government capacity but also a cohesive system of public, private, and volunteer groups integrated into the community (Olshansky et al. 2012). Research consistently shows that community recovery from disasters can be greatly enhanced by ensuring that the preexisting social environment supports the recovery process.

Resilience in a Recovery Context

In a recovery context, a resilient community is one that can cope with, adapt to, and recover from the loss and disruption encountered through the experience of a disaster. How effectively this is done is a function of how well people, communities, and societies can work together and use their resources to deal with the problems encountered. This entry discusses recovery in relation to community and societal recovery. In the entry we draw largely on recent experiences following the 2011 Christchurch, New Zealand, earthquake from the perspective of people's accounts of what they had to contend with and how they responded to the disruption and challenges encountered during the recovery. We also draw on experiences gained from research in other cultures to illustrate the similarities and differences that culture introduces into how earthquake recovery can be understood and managed. The first issue addressed concerns what people had to contend with and how these demands changed over the course of recovery.

The Adaptive Demands of Earthquake Recovery

The Christchurch recovery experience illustrates several issues that need to be considered when conceptualizing community recovery following earthquakes. The first is that recovery is a process rather than any specific activity and one that extends over time as people deal with demands and challenges that differ depending on the stage of response and recovery they are at. This is depicted in Fig. 1 as the time arrow

Community Recovery Following Earthquake Disasters, Fig. 1 A summary of how adaptive capacities at person, family, household, and societal levels interact to influence earthquake recovery (Adapted from Paton et al. 2014)

illustrates how the relative salience of recovery issues and demands changes with time (Paton et al. 2014). For example, during the immediate impact phase (e.g., 3–14 days depending on nature and intensity of impact), the destruction of infrastructure and loss of essential services means that the demands people must cope with and adapt to relate people’s ability (“self-reliance”) to meeting survival needs on their own or with their neighbors. Over time, as essential services are progressively restored but while normal societal and economic activities remain affected, the challenges and issues people have to contend with change. As people move into the response phase, they find themselves working with neighbors and community members to deal with local issues (e.g., effecting basic repairs, looking after more vulnerable members of their community, etc.) and dealing with issues relating

to employment and livelihood. As the event moves into the recovery phase, people can increasingly find themselves dealing with demands from dealing with, for example, government agencies and insurance companies. The relative salience of these “adaptive demands” (i.e., what people have to adapt to and cope with) changes over time (Fig. 1). A second issue highlighted by the Christchurch experience was the fact that people may have transition through response and recovery cycles several times as they deal with the consequences of multiple aftershocks. This is illustrated in the aftershock feedback loop in Fig. 1. A third issue arises from the fact that differences were evident in how well people and communities dealt with these adaptive demands (Olshansky et al. 2006; Paton et al. 2014). This introduces a need to identify the sources of such variability in “adaptive capacity.”

Mitigation and Structural Preparedness

While recovery takes place in the aftermath of the hazard event, how well people, communities, and societies recover is a function of what they have to mitigate their risk and how well they have prepared to deal with those aspects of risk that cannot be readily anticipated (e.g., the degree of localized losses). Mitigation activities such as land use planning and building codes and the steps residents have taken to secure the structural integrity of their homes (Fig. 1) have an important bearing on the speed of earthquake recovery. With regard to community recovery, the importance of these pre-event activities reflects the fact that having a home that survives the initial impact reduces the risk of injury and death to its inhabitants. It also increases the likelihood of people having a habitable building in which to base their recovery activities and increases people's availability to offer assistance to neighbors and others and to contribute to economic recovery. However, people differ in the degree to which they take steps to safeguard their homes. This provides insights into the predictors of preparedness that can be defined as adaptive capacities (Paton and Johnston 2006). For example, the level of people's earthquake knowledge and family beliefs about the importance of structural preparedness offers insights in differences in community recovery capacity (Fig. 1). Thus, prevailing levels of structural and survival readiness provide the foundation for effective recovery when people face the emergent issues that arise.

Personal and Community Adaptive Capacity

The effectiveness of initial earthquake recovery is also influenced by people's capacity for self-reliance and their ability to deal with the immediate challenges of coping with earthquake consequences. The adaptive capacities that help explain differences in people's ability to do so are influenced by factors such as their earthquake knowledge, self-reliance, and family beliefs in preparedness (Fig. 1). Emergent recovery issues

include being able to develop self-help groups with neighbors and others to deal with local problems (e.g., removing rubble, setting up community meeting places, etc.). Subsequently, reestablishing community groups or forming new ones (e.g., organizing local efforts to repair homes, identifying and meeting local needs) affects the quality of recovery (Paton et al. 2014). Differences in how well these emergent demands are dealt with are influenced by family preparedness beliefs and factors such as levels of community competence and community leadership (Fig. 1). For example, confidence in self-help capability and the ability to engage with others under novel circumstances to confront issues is important (Paton et al. 2014). Developing a group identity, by increasing people's commitment to the recovery of the community and its members, which makes an additional and important contribution to recovery (Winstanely et al. 2011), and willingness to volunteer all contribute to explaining differences in levels of community earthquake recovery.

Key characteristics of community members (Mamula-Seadon et al. 2012; Norris et al. 2008; Paton and Johnston 2006) include willingness to be proactive despite the novelty in their circumstances, taking steps to include as many residents as possible, and empowering, encouraging, and supporting community initiatives. A need for new, community-specific ways of communication that address specific and diverse community needs and that are available when people need it was also identified as playing a significant role in expediting community recovery (Winstanely et al. 2011). A common characteristic of community groups is that the key roles within them are filled by volunteers.

Volunteering

Volunteering includes things ranging from assisting welfare services to organizing social events to working directly with agencies. Volunteering has secondary effects in that it helps people feel a sense of control in otherwise uncontrollable circumstances. This can be very

important in earthquake recovery as aftershock sequences can result in people cycling through response and recovery several times over what can be a prolonged period of recovery. Volunteering also increases opportunities for people to be actively involved in community life (cf. community participation) in meaningful ways (e.g., doing something of value for others) and helping rebuild the social fabric of the community. Volunteering not only provides community members with access to social support but also provides opportunities for people to work on issues of shared significance and develop problem-solving and planning skills. These activities result in the development and maintenance of constructs such as community participation and collective efficacy that have been recognized as playing key roles in community resilience and the development of social capital (e.g., Norris et al. 2008; Paton 2008). The quality of people's recovery is also influenced by how well community members and recovery agencies interact.

Community-Agency Adaptive Capacity

Given the atypical and threatening nature of the demands encountered, recovery is influenced by how well citizens and groups can represent their needs to agencies and can secure the resources each community needs to take responsibility for their unique recovery (Collins et al. 2011). These needs range from dealing with loss of utilities and dealing with residents with special needs to dealing with government agencies over the course of a prolonged period of recovery.

A pivotal predictor of recovery is proactive community leadership. Emergent community-based leaders help bring people together, facilitate a coherent community response, and link the community with external agencies and specialists to secure the resources and help required to meet local needs (Paton et al. 2014; Paton and Jang 2014). Thus, leadership is a crucial community resource and one that plays a critical role in empowering community recovery (Norris et al. 2008; Paton 2008). This is illustrated by the two-way arrow that links community and

society through community leadership. Community recovery may call for multiple leaders (e.g., managing community recovery versus managing specialist activities such as organizing repair work). Because those filling leadership roles will be volunteers, training and support for them is important.

The leadership, community processes, and volunteer activities discussed above represent resources that contribute to creating empowered communities. However, in complex disaster recovery environments, communities also need information and resources that cannot be met from within the community but only from the wider societal context: from NGOs, government agencies, and businesses. The quality of the relationships between communities and NGOs, government, and businesses that evolve in the recovery environment will thus influence the degree to which communities are empowered to enact their own recovery initiatives. This introduces a need to consider how relationships with NGOs, government, and businesses influence recovery.

The important role that relationships with government and businesses played in meeting community needs was endorsed in people's accounts of what helped and hindered community recovery in Christchurch (Mamula-Seadon et al. 2012; Paton et al. 2014). It is, however, important to appreciate that the relationship between community recovery and business and economic recovery is one characterized by interdependence (e.g., community members can be employees and consumers) and not just as one defined in terms of agencies and businesses being unidirectional providers of resources to communities (Paton and McClure 2013). Notwithstanding, the latter is important.

Communities can influence their relationship with government agencies and businesses by being proactive. This is illustrated by the two-way arrows in Fig. 1 that depict how community competency and leadership help link people and communities to societal agencies. In Christchurch, recovery was facilitated by community leaders taking active steps to represent community needs to government departments,

NGOs, and businesses rather than waiting for them to come to the community. Facilitation was increased also by agencies working through community leaders. However, when it comes to the ability and effectiveness of a proactive community-led approach to dealing with government agencies, the extent to which this relationship marginalizes or facilitates community recovery is affected by things such as the governance mechanisms setup as part of the formal recovery response (Bach 2012; Collins et al. 2011). Bureaucracies often do not adapt well to this circumstance, and new governmental organizations typically emerge to provide more resources. It is important to appreciate that the quality of earthquake recovery is a reciprocal process. That is, it will only arise when communities and government agencies, NGOs, and businesses play complementary roles in facilitating comprehensive recovery. Thus, while societal-level agencies play key roles in passing appropriate legislation and providing resources, these activities must be developed in ways that empower communities. This is depicted in Fig. 1 by the two-way arrow linked to empowerment and trust.

Earthquake Recovery and Community Development

Recovery is also about facilitating development. The concept of “Building Back Better” applies to the social and the physical environment. The physical issues requiring attention include land use planning, building codes, and architecture. Social rebuilding requires the inclusion of other strategies. For example, in Christchurch, a Psychosocial Recovery Advisory Group (PRAG) was developed to provide expert, timely, quality evidence-based advice on psychosocial issues (Mooney et al. 2011). The PRAG adopted a strengths-based approach for conceptualizing recovery and facilitating longer-term social development. The strengths-based approach mobilizes cultural, spiritual, and social resources with an emphasis on development through community participation and engagement. It is thus

an example of a strategy that contributes to creating empowered communities and providing a platform for social development.

Development will be further facilitated by developing a comprehensive Canterbury Recovery Strategy. Long-term recovery is facilitated by planning that covers, for example, built heritage, education, Maori, and community development in ways that build social and cultural capital.

The Christchurch experience also highlights caution in making recovery decisions when a community is under stress. There are challenges in getting communities to participate in complex decision-making in times of stress immediately after a disaster event, as well as delaying such decisions during the recovery period. Ensuring that communities are participating in decision-making processes prior to an event can help alleviate some of these problems. The importance of the latter is reinforced by the inclusion of a cross-cultural perspective on earthquake recovery.

Because earthquakes occur in many different countries, developing a comprehensive understanding of earthquake recovery makes it pertinent to consider the similarities and differences that the associated social and cultural diversity introduces into the recovery process. While this is an area requiring more research, it is possible to advance this understanding by comparing countries that differ in their respective cultural characteristics. For example, in countries with a relatively individualist cultural orientation (e.g., New Zealand), people act consistently across situations in accordance with a self-concept that is relatively independent of social situation and in which achieving personal goals is a prominent objective. In contrast, in collectivist countries like Taiwan, actions are underpinned by culturally embedded beliefs that are reflected in shared purpose and activity involving alignment with social norms, achieving collective goals, and engaging in activities related to future goals that emphasize social relations (Paton and Jang 2014). Comparing these countries can provide a foundation for development of a comprehensive understanding of earthquake recovery.

Based on some preliminary research comparing New Zealand (populations affected by the 2011 Christchurch earthquake) and Taiwan (those affected by the 1999 Chi Chi earthquake) (Paton and Jang 2014), people in Christchurch and Taiwan (Tung Shia) endorsed the fact that earthquake recovery was influenced by survival, household planning, neighborhood self-help, psychological, and community-agency factors. Irrespective of culture or location, people face the same challenges. However, both similarities and differences were evident in how people responded and recovered.

The work in Taiwan involved an ethnic minority group, the Hakka that account for some 20 % of the Taiwanese population. They were the group most significantly affected by the Chi Chi earthquake. Similarities between the social processes that influenced earthquake recovery were evident in both Taiwan and New Zealand. Both populations endorsed the need for self-reliance, active community involvement, leadership, and communities being proactive in managing their own recovery activities. The fact that government agencies could help or hinder community recovery was also identified as an important determinant of community recovery following a significant seismic event. However, some cultural differences in how this was achieved were evident when the two countries were compared.

In Taiwan, the nature of the social recovery was strongly influenced by the Hakka spirit, the essence of Hakka culture, which comprises characteristics such as frugality, diligence, self-reliance, shared responsibility, and persistence (Paton and Jang 2014). Residents highlighted the key role that Hakka spirit played in their recovery following the Chi Chi earthquake. For example, it was identified as generating a sustained sense of purpose, self-reliance, and perseverance (which creates a kind of culture-specific self-efficacy) throughout the several years of their recovery and facilitated people's efforts to rebuild both their homes and their communities.

Recovery was also facilitated by the influence of Hakka beliefs regarding the importance of accepting disasters as part of life experience,

accepting that the earthquake and its consequences had occurred, and the importance of moving on in ways that emphasized adopting a problem-focused coping approach to their adaptive recovery. Spiritual beliefs were also implicated. Spiritual beliefs helped people cope with challenges, be more optimistic, to focus on the positive aspects of their experience (e.g., how everyone pulled together to promote the recovery of the whole community), accept their losses, and adopt a problem-focused approach to their problem solving. Spirituality influenced residents' acceptance of earthquake consequences, enhanced their sense of community, and strengthened their social support networks.

The comparative New Zealand-Taiwan analyses illustrate how everyday or mainstream community and cultural competencies and characteristics (e.g., the community participation and collective efficacy variables reflect the outcomes of people's accumulated experience of community life) influence on people's ability to cope with, adapt to, and recover from earthquakes. However, the discussion also highlighted a need to accommodate cultural differences in the development and delivery of earthquake recovery interventions.

Summary

In conclusion, the quality of people's earthquake recovery is a function of their ability to deal with survival and planning issues (e.g., having water and being able to develop household and neighborhood plans to deal with the immediate impact of an earthquake), being able to confront psychological and livelihood/economic disruption, and being able to work with government agencies and NGOs. How well people and communities can deal with these demands and recover effectively is a function of the degree to which several personal and community competencies are present. These include self-efficacy, place attachment, active community participation, collective efficacy, empowerment, trust, community leadership, inclusivity, and sense of community.

Complex fractional moments; Earthquake ground motion; Fractional calculus; Gaussian zero-mean excitation; Mellin transform; Riesz fractional integrals; Stochastic analysis

Introduction

Fractional calculus is referred to derivatives and integrals of order $\beta \in \mathbb{R}^+$ or more generally to complex order $\gamma = \rho + i\eta$, $\rho \in \mathbb{R}^+$, $\eta \in \mathbb{R}^+$. There are many different definitions of fractional operators such as Riemann-Liouville, Riesz, Marchaud, Caputo, etc. (see, e.g., Podlubny 1999; Samko et al. 1993). The various definitions differ with each another by intervals of integration or are simply adaptations of the Riemann-Liouville ones. In any case all the fractional operators share some common points:

- All the fractional operators are convolution integrals with power law kernel.
- For all fractional operators, the rules of classical derivatives and integrals (*linearity, semi-group, Leibniz rule*, etc.) hold.

- In the Fourier and in Laplace domains, they exactly behave like the derivatives and integrals of integer order.

For all these reasons, it will be more appropriate to call such operators as *generalized derivatives* and *integrals*, but for historical reasons all the people continue to call them as *fractional* ones.

In the last half century, fractional calculus becomes more and more popular also among the communities of physicists and engineers. This is due to its versatility to describe dynamic properties of the systems in many fields such as electrochemistry, thermal engineering, electricity, stochastic dynamics, and mechanics and especially to describe viscoelasticity.

In this entry some relevant examples on the use of fractional calculus to earthquake ground motion modeled as a stationary normal colored noise are presented. Applications of fractional calculus for the description of mono- and multivariate earthquake accelerations and exact filter equation are obtained in an integral form involving Riesz fractional operator in zero. The latter are related to complex spectral moments by Mellin transform operator. Other relevant application in probability may be found in Cottone et al. (2010) and Di Paola and Pinnola (2012).

Some Basic Elements of Fractional Calculus

Hereinafter some few preliminary definitions of fractional calculus are introduced for clarity sake's as well as for introducing appropriate symbologies. Let us start with the definition of the Cauchy formula for multiple integrals

$$\begin{aligned} (I_{a^+}^n f)(t) &= \int_a^t dt_1 \int_a^{t_1} \dots \int_a^{t_{n-1}} f(\tau) d\tau \\ &= \frac{1}{(n-1)!} \int_a^t (t-\tau)^{n-1} f(\tau) d\tau; \quad n \in \mathbb{N} \end{aligned} \quad (1)$$

Equation 1 shows that the n -th primitive of $f(t)$ may be obtained as a convolution integral

with power law kernel. The fractional integral is the generalization of Eq. 1 to an arbitrary order β in the form

$$(I_{a^+}^\beta f)(t) = \frac{1}{\Gamma(\beta)} \int_a^t (t-\tau)^{\beta-1} f(\tau) d\tau; \quad \beta > 0 \quad (2)$$

where $\Gamma(\cdot)$ is the Euler-Gamma function that interpolates the factorials ($\Gamma(n-1) = n!$). $(I_{a^+}^\beta f)(t)$ is referred as *Riemann-Liouville (RL) fractional integral*. The suffix a^+ stands for the initial time at which the operator applies and the apex $+$ means that t in Eq. 2 is greater than a . For this reason $(I_{a^+}^\beta f)(t)$ is called *left RL fractional integral*. The value a may be also $-\infty$ and in this case in literature is written $(I_{-\infty^+}^\beta f)(t)$ or simply $(I_{+}^\beta f)(t)$. The *right RL fractional integral* still exists and the integration is performed in $t \div a$, $a > t$. The *right RL* is usually written as $(I_{a^-}^\beta f)(t)$, and if $a \rightarrow \infty$ then is written as $(I_{-\infty^-}^\beta f)(t)$ or simply $(I_{-}^\beta f)(t)$.

As the derivative of order n may be viewed as the derivative of order $m+n$ of the m -th primitive, the Riemann-Liouville fractional derivative is defined as

$$\begin{aligned} (D_{a^+}^\beta f)(t) &= \frac{1}{\Gamma(n-\beta)} \frac{d^n}{dt^n} \int_a^t (t-\tau)^{n-\beta-1} f(\tau) d\tau; \\ \beta > 0 \end{aligned} \quad (3)$$

where $n = [\beta] + 1 \in \mathbb{N}$ and $[\beta]$ means *integer part* of β . The definition of left and right RL fractional derivative is like for the RL fractional integrals, then we denote $(D_{a^+}^\beta f)(t)$ if $t < a$, or if $a \rightarrow \infty$, we denote $(D_{-\infty^+}^\beta f)(t)$ or simply $(D_{+}^\beta f)(t)$ and similarly for the right RL derivative. Other notations are used by different authors, and here the notation of Samko et al. (1993) has been adopted. RL fractional integrals and derivatives remain meaningful also for complex order $\gamma = \rho + i\eta$.

In the following the fractional operators are always defined for complex order. All the rules of classical derivatives and integrals of integer order

still apply also for fractional order operators including semigroup properties, integration by parts, etc. Moreover, in Fourier and Laplace domains, RL fractional operators exactly behave like the classical derivatives and integrals. Such an example, by denoting the Fourier transform operator of $f(t)$ as $F_{\mathcal{F}}(\omega)$ defined as

$$\mathcal{F}\{f(t); \omega\} = \int_{-\infty}^{\infty} \exp(i\omega t) f(t) dt = F_{\mathcal{F}}(\omega) \quad (4)$$

we have

$$\begin{aligned} \mathcal{F}\left\{\frac{d^n f(t)}{dt^n}; \omega\right\} &= (-i\omega)^n F_{\mathcal{F}}(\omega); \\ \mathcal{F}\left\{(D_{0+}^{\gamma} f)(t); \omega\right\} &= (-i\omega)^{\gamma} F_{\mathcal{F}}(\omega) \end{aligned} \quad (5a)$$

$$\begin{aligned} \mathcal{F}\{I^n f(t); \omega\} &= (-i\omega)^{-n} F_{\mathcal{F}}(\omega); \\ \mathcal{F}\left\{(I_{0+}^{\gamma} f)(t); \omega\right\} &= (-i\omega)^{-\gamma} F_{\mathcal{F}}(\omega) \end{aligned} \quad (5b)$$

Similar behavior may be readily found in Laplace domain (see, e.g., Podlubny 1999).

In order to derive the filter equations, we need of other two relevant definitions: the *Riesz fractional operator* and the *Mellin transform*.

The RL fractional operators are related to the evolution of $f(t)$ into an assigned interval $(a \div t)$. In some cases, like in the probability domain or in power spectral density domain, the functions are defined in the whole range $-\infty \div \infty$. In these cases it is important to extend the RL fractional operators to unbounded domain. The extensions of the RL operator in unbounded domain are the *Riesz fractional integrals and derivatives*. These operators are a combination of left and right RL operators. Riesz fractional integrals and derivatives are in the following denoted as $(I^{\gamma} f)(t)$ and $(D^{\gamma} f)(t)$, respectively, and are defined as

$$\begin{aligned} (I^{\gamma} f)(t) &= \frac{1}{2v_c(\gamma)} \int_{-\infty}^{\infty} |t - \tau|^{\gamma-1} f(\tau) d\tau \\ &= \frac{\Gamma(\gamma)}{2v_c(\gamma)} [(I_{+}^{\gamma} f)(t) + (I_{-}^{\gamma} f)(t)] \end{aligned} \quad (6)$$

$$\begin{aligned} (D^{\gamma} f)(t) &= \frac{1}{2v_c(1-\gamma)} \int_{-\infty}^{\infty} |\tau|^{-\gamma-1} (f(t-\tau) - f(t)) d\tau \\ &= \frac{\Gamma(\gamma)}{2v_c(\gamma)} [(D_{+}^{\gamma} f)(t) + (D_{-}^{\gamma} f)(t)] \end{aligned} \quad (7)$$

where $v_c(\gamma) = \Gamma(\gamma) \cos(\gamma\pi/2)$, $\gamma = \rho + i\eta$, $\rho > 0$, $\rho \neq 1, 3, \dots$.

Fourier transform of the Riesz operator for $0 < \rho < 1$ is given as (see Samko et al. 1993, p. 217)

$$\mathcal{F}\{(I^{\gamma} f)(t); \omega\} = |\omega|^{-\gamma} F_{\mathcal{F}}(\omega) \quad (8a)$$

$$\mathcal{F}\{(D^{\gamma} f)(t); \omega\} = |\omega|^{\gamma} F_{\mathcal{F}}(\omega) \quad (8b)$$

From Eqs. 8a and 8b it may be stated that, for Fourier transformable functions, $(I^{-\gamma} f)(t) = (D^{\gamma} f)(t)$. This property is valid only for $0 < \rho < 1$ and Fourier transformable functions.

Lastly the Mellin transform operator is defined as

$$\begin{aligned} \mathcal{M}\{f(t); \gamma\} &= \int_0^{\infty} f(t) t^{\gamma-1} dt = F_{\mu}(\gamma); \\ \gamma &= \rho + i\eta \end{aligned} \quad (9)$$

Inverse Mellin transform returns $f(t)$ in the form

$$\begin{aligned} f(t) &= \mathcal{M}^{-1}\{F_{\mu}(\gamma); t\} \\ &= \frac{1}{2\pi i} \int_{\rho-i\infty}^{\rho+i\infty} F_{\mu}(\gamma) t^{-\gamma} d\gamma; \quad t > 0 \end{aligned} \quad (10)$$

From Eq. 9 it may be observed that integration is performed along the imaginary axis while ρ remains fixed. This observation has important consequences on how it will be better explained later on. Moreover, it may be observed that $F_{\mu}(\gamma)$ is a complex function having even real part and odd imaginary part with respect to η , that is, $F_{\mu}(\rho + i\eta) = F_{\mu}^*(\rho - i\eta)$, where the star means complex conjugate.

Condition of existence of Mellin transform and its inverse is $-\rho < \rho < -q$, where p and

q refer to the asymptotic behavior of $f(t)$ at $t \rightarrow 0$ and $t \rightarrow \infty$, respectively:

$$\lim_{t \rightarrow 0} x(t) = \mathcal{O}(t^p); \quad \lim_{t \rightarrow \infty} x(t) = \mathcal{O}(t^q) \quad (11)$$

where $\mathcal{O}(\cdot)$ means *order* of the term in parenthesis. Such an example if $f(t) = 1/(1+t)$, $\lim_{t \rightarrow 0} f(t) = 1$, then $p = 0$, $\lim_{t \rightarrow 0} f(t) = t^{-1}$ then $q = -1$. It follows that $f(t) = 1/(1+t)$ is Mellin transformable as the real part of γ is selected in the range $0 < \rho < 1$. The strip $-p \div -q$ is called *fundamental strip* (FS) of the Mellin transform. In discretized form Eq. 10 may be also rewritten as

$$\begin{aligned} f(t) &\simeq \frac{\Delta\eta}{2\pi} \sum_{k=-m}^m F_{\mu}(\gamma_k) t^{-\gamma_k} \\ &= \frac{1}{2b} t^{-\rho} \sum_{k=-m}^m F_{\mu}(\gamma_k) \left[\cos\left(k \frac{\pi}{b} \xi\right) - i \sin\left(k \frac{\pi}{b} \xi\right) \right] \end{aligned} \quad (12)$$

where $\gamma_k = \rho + ik\Delta\eta$, $b = \pi/\Delta\eta$, and $\xi = \ln t$. The number m of the summation in Eq. 12 gives a cutoff value along the imaginary axis and is selected in such a way that terms of order $m+n$ do not produce sensible variations on $f(t)$. It is to be stressed that Eq. 12 is independent of the value of ρ selected, provided it belongs to the FS of the Mellin transform. This is due to the fact that the Mellin transform $F_{\mu}(\gamma)$ is holomorph into the FS.

From Eq. 12 some considerations may be withdrawn:

- Inverse Mellin transform returns $f(t)t^{\rho}$ in the domain ξ and looks as a Fourier series, and $F_{\mu}(\gamma_k)/2b$ are the (complex) coefficients of the series.
- In the range $e^{-b} \div e^b$, the trigonometric functions $\exp(-ik \frac{\pi}{b} \ln t)$ are orthogonal, and as $m \rightarrow \infty$ they form a basis in such an interval. It follows that the orthogonality condition in ξ domain is in $-b \div b$.
- The factor $t^{-\rho}$ in Eq. 12 ensures us that $f(t)$ tends to zero as $t \rightarrow \infty$, while in zero Eq. 12, unless $f(0) = 0$, gives an infinite value due to the factor $t^{-\rho}$. Apart from this pathological behavior in $t = 0$, all the function $f(t)$ is

overlapped by summation (12) including the trend at $t = \infty$.

For more informations on fractional calculus, integration of fractional differential equation, readers are referred to the books of Miller and Ross (1993), Samko et al. (1993), Gorenflo and Mainardi (1997), and Podlubny (1999).

Power Spectral Density, Correlations, and Spectral Moments

The simplest model of earthquake acceleration $\ddot{Z}_g(t)$ is that it is represented as a stochastic stationary zero mean colored normal process. In this case the power spectral density (PSD) function, or its inverse Fourier transform, namely, the autocorrelation function, fully describes the process $\ddot{Z}_g(t)$ in probabilistic setting. In the following, for simplicity of notation, $\ddot{Z}_g(t)$ will be indicated as $Y(t)$. More realistic models may be found in literature giving a variety of nonstationary models. Among them the so-called *uniformly* modulated (Shinozuka and Sato 1967) have been proposed. These processes are constructed as the product of a stationary process, with assigned PSD, and a deterministic modulating function. Modulation in frequency and time has been proposed by Solomos and Spanos (1984), Shinozuka and Deodatis (1988), and Conte and Peng (1997).

For simplicity's sake, in this entry, we confine ourselves to the stationary model. In order to define the stationary seismic motion, two strategies are commonly assumed:

- The seismic ground acceleration is thought as a filtered normal white noise.
- The PSD is modeled in such a way that the corresponding response spectrum of accelerograms generated by the PSD matches the target one.

In the former case, the equation of filter, usually a system of differential equation of integer order, is already known, but the selection of the various parameters to model the effective

behavior of the ground deposit requires a level of knowledge that is seldom available.

On the other hand, the PSD consistent with the target response spectrum gives a shape of PSD (Falsone and Neri 1999; Cacciola et al. 2004) in frequency domain, whose parameters of the filter equation may not be easily obtained by using classical differential equations. In this regard discrete autoregressive (AR) or moving-average (MA) or their combination ARMA models have been proposed in literature (Spanos 1983, 1986) to generate sample functions with assigned PSD or correlation function.

In section “Filter Equation,” the issue of the definition of the filter equations for any shape of PSD will be addressed.

Fractional Spectral Moments

In the analysis of stochastic processes, an important role is played by the so-called spectral moments (SM), introduced by Vanmarcke (1972), important for the definition of some characteristics of stochastic processes and in reliability analysis (Michaelov et al. (1999)). These quantities are defined as the moments of the one-sided PSD with respect to the frequency origin. Let $S_Y(\omega)$ be the PSD of the earthquake acceleration with $S_Y(\omega) = S_Y(-\omega)$. Let $G_Y(\omega)$ be the *one-sided* PSD defined

$$G_Y(\omega) = 2U(\omega)S_Y(\omega) \quad (13)$$

being $U(\omega)$ the unit step function.

The SM are the moments of $G_Y(\omega)$ with respect to the frequency origin that is

$$\begin{aligned} \lambda_Y^j &= \int_{-\infty}^{\infty} 2U(\omega)\omega^j S_Y(\omega) d\omega \\ &= \int_0^{\infty} G_Y(\omega)\omega^j d\omega \end{aligned} \quad (14)$$

As a particular case, λ_Y^0 and λ_Y^2 represent the variance of the process $Y(t)$ and of $\dot{Y}(t)$, respectively. More informations on spectral moments may be found in Di Paola and Petrucci (1990), Muscolino (1991), and Spanos and Miller (1994). The spectral moments λ_Y^j are not able to describe

neither the PSD nor the correlation of the process $Y(t)$ itself because they may be divergent quantities starting from an assigned order. As an example for the classical Tajimi-Kanai filter, the spectral moments diverge for $j \geq 4$.

An extension of the definition given in Eq. 14 is obtained in the form $\lambda_Y^{\gamma-1}(\gamma \in \mathbb{C})$ in the following denoted as $\Lambda_Y(\gamma - 1)$ defined as

$$\Lambda_Y(\gamma - 1) = \int_0^{\infty} G_Y(\omega)\omega^{\gamma-1} d\omega \quad \gamma = \rho + i\eta \quad (15)$$

that is a complex function representing the Mellin transform of the one-sided PSD $G_Y(\omega)$. The function $\Lambda_Y(\gamma - 1)$ will be called *fractional spectral moment* (FSM) function. On the other hand, the inverse Mellin transform returns $G_Y(\omega)$ and $S_Y(\omega)$ in the form

$$\begin{aligned} G_Y(\omega) &= \frac{1}{2\pi i} \int_{\rho-i\infty}^{\rho+i\infty} \Lambda_Y(\gamma - 1)\omega^{-\gamma} d\gamma \\ &\simeq \frac{1}{2b} \sum_{k=-m}^m \Lambda_Y(\gamma_k - 1)\omega^{-\gamma_k}; \quad \omega \\ &> 0 \end{aligned} \quad (16a)$$

$$S_Y(\omega) \simeq \frac{1}{4b} \sum_{k=-m}^m \Lambda_Y(\gamma_k - 1)|\omega|^{-\gamma_k} \quad (16b)$$

where $\gamma_k = \rho + ik + \Delta\eta$, $b = \pi/\Delta\eta$, and $m\Delta\eta = \bar{\eta}$ is a cutoff value along the imaginary axis appropriately selected.

Equations 16a and 16b remain valid provided ρ belongs to the FS of the Mellin transform of $G_Y(\omega)$. Such an example for the Tajimi-Kanai (1960) PSD, since $\lim_{\omega \rightarrow 0} G_Y(\omega) = 4\pi S_0(\mathcal{O}(\omega^0))$, being S_0 the (finite) PSD of the white noise, and $\lim_{\omega \rightarrow \infty} G_Y(\omega) = \omega^{-2}(\mathcal{O}(\omega^{-2}))$, then the FS for the Tajimi-Kanai filter is $0 < \rho < 2$. Since $\Lambda_Y(\gamma_k - 1)$ never diverge provided ρ belongs to the FS of $G_Y(\omega)$, the whole $G_Y(\omega)$ is restored with the expansion in Eq. 16 with exception of the value in zero. It is to be stressed that truncation of the series up to the first m terms does not produce the divergence at $\omega \rightarrow \infty$.

Now we define the correlation function of the ground acceleration as $R_Y(\tau) = E[Y(t)Y(t+\tau)]$, where $E[\cdot]$ denotes ensemble average. By making the Fourier transform of the Riesz integral, according to Eq. 8a, we obtain

$$\mathcal{F}\{(I^{1-\gamma}R_Y)(t), \omega\} = |\omega|^{\gamma-1}S_Y(\omega); \quad 0 < \rho < 1 \quad (17)$$

It follows that $(I^{1-\gamma}R_Y)(t)$ is the inverse Fourier transform of $|\omega|^{\gamma-1}S_Y(\omega)$, that is,

$$(I^{1-\gamma}R_Y)(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i\omega t} |\omega|^{\gamma-1} S_Y(\omega) d\omega \quad (18)$$

Since $S_Y(\omega)$ is symmetric, by putting $t = 0$ in Eq. 18, we get

$$\begin{aligned} (I^{1-\gamma}R_Y)(0) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} |\omega|^{\gamma-1} S_Y(\omega) d\omega \\ &= \frac{1}{2\pi} \int_0^{\infty} |\omega|^{\gamma-1} G_Y(\omega) d\omega = \frac{1}{2\pi} \Lambda_Y(\gamma-1) \end{aligned} \quad (19)$$

As a conclusion $2\pi(I^{1-\gamma}R_Y)(0)$ is the Mellin transform of the one-sided PSD, namely, the FSM of the one-sided PSD $G_Y(\omega)$. From Eq. 19 it may be recognized that the FSM may be evaluated as the moment of the one-sided PSD or by evaluating the Riesz fractional integrals in zero of the correlation function. It is to be remarked that if $\Lambda(\gamma-1)$ is evaluated for a certain value ρ , the FSM for any other value of $\rho - \alpha$ may be easily evaluated provided $\rho - \alpha$ belongs to the FS of Mellin transform (see “Appendix”).

By inserting Eq. 19 in 16, the one-sided PSD may also be represented as follows

$$G_Y(\omega) \simeq \frac{\pi}{b} \sum_{k=-m}^m (D^{\gamma_k-1}R_Y)(0) \omega^{-\gamma_k}; \quad (20a)$$

$$\gamma_k = \rho + ik\Delta\eta; \quad \omega > 0$$

$$S_Y(\omega) \simeq \frac{\pi}{2b} \sum_{k=-m}^m (D^{\gamma_k-1}R_Y)(0) |\omega|^{-\gamma_k} \quad (20b)$$

The representation of $G_Y(\omega)$ in the form of Eq. 20a reveals that $G_Y(\omega)$ is expressed in a

generalized Taylor series. The difference with the classical Taylor series is that in the latter series the coefficients are the derivatives of the given function in zero and in Eqs. 20a and 20b are the fractional derivative in zero. Since in the FS the various FSMs never diverge and $|\omega|^{-\gamma_k}$ remains finite (provided ρ belongs to the FS), the whole PSD is restituted by Eq. 16b or 20b.

Fractional Spectral Moments of the Correlation function

It is to be emphasized that by using integer order derivatives of the correlation function, we get

$$\mathcal{F}\left\{\frac{d^j R_Y(\tau)}{d\tau^j}; \omega\right\} = (-i\omega)^j S_Y(\omega) \quad (21)$$

and its inverse Fourier transform returns $d^j R_Y(\tau)/d\tau^j$ in the form

$$\left[\frac{d^j R_Y(\tau)}{d\tau^j}\right] = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i\omega\tau} (-i\omega)^j S_Y(\omega) d\omega \quad (22)$$

By evaluating $d^j R_Y(\tau)/d\tau^j$ in $\tau = 0$, we get $[d^j R_Y(\tau)/d\tau^j]_{\tau=0} = (-i)^j \lambda_Y^j / \pi (j = 0, 2, \dots)$ and is zero for $j = 1, 3, 5, \dots$. It follows that the classical Taylor series of the correlation is given as

$$R_Y(\tau) = \frac{1}{\pi} \sum_{j=0,2}^{\infty} \frac{(-i)^j}{j!} \lambda_Y^j \tau^j \quad (23)$$

We have already observed that the classical spectral moments may be divergent quantities, and then the classical Taylor series (23) becomes meaningless. On the other hand, also if the spectral moments do not diverge, truncation of the series (23) always produces the undesired phenomenon, that is, $\lim_{\tau \rightarrow \infty} R_Y(\tau) = \infty$.

Starting from the correlation function, we may define the one-sided correlation

$$C_Y(\tau) = 2U(\tau)R_Y(\tau) \quad (24)$$

and then the Mellin transform of $C_Y(\tau)$ is defined as

$$\mathcal{M}\{C_Y(\tau); \bar{\gamma}\} = \int_0^\infty \tau^{\bar{\gamma}-1} C_Y(\tau) d\tau = \Theta_Y(\bar{\gamma} - 1) \quad (25)$$

that are the spectral moments of the correlation function. Inverse Mellin transform of Eq. 25 returns $C_Y(\tau)$ in the form

$$C_Y(\tau) = \frac{1}{2\pi i} \int_{\bar{\rho}-i\infty}^{\bar{\rho}+i\infty} \Theta_Y(\bar{\gamma} - 1) \tau^{-\bar{\gamma}} d\bar{\gamma} \\ \cong \frac{\Delta\eta}{2\pi} \sum_{k=-m}^m \Theta_Y(\bar{\gamma}_k - 1) \tau^{-\bar{\gamma}_k}; \quad \tau > 0 \quad (26)$$

and as usual $\bar{\gamma}_k = \bar{\rho} + ik\Delta\eta$. Because of the symmetry of $R_Y(\tau)$, the latter may be found in the form

$$R_Y(\tau) \cong \frac{\Delta\eta}{4\pi} \sum_{k=-m}^m \Theta_Y(\bar{\gamma}_k - 1) |\tau|^{-\bar{\gamma}_k}; \quad \tau > 0 \quad (27)$$

Fourier transform of Eq. 27 restitutes $S_Y(\omega)$ in the form

$$S_Y(\omega) = \frac{\Delta\eta}{2\pi} \sum_{k=-m}^m \Theta_Y(\bar{\gamma}_k - 1) \Gamma(1 - \bar{\gamma}_k) \sin\left(\frac{\bar{\gamma}_k \pi}{2}\right) |\omega|^{\bar{\gamma}_k-1} \quad (28)$$

By letting $\bar{\gamma}_k - 1 = -\gamma_k$, Eq. 28 may be rewritten as

$$S_Y(\omega) = \frac{1}{2b} \sum_{k=-m}^m \Theta_Y(-\gamma_k) v_c(\gamma_k) |\omega|^{-\gamma_k} \quad (29)$$

Comparison with the expression given in Eq. 16b reveals that

$$\Lambda_Y(\gamma_k - 1) = 2\Theta_Y(-\gamma_k) v_c(\gamma_k) \quad (30)$$

From this equation it may be recognized that the FSM may be also evaluated directly from the correlation function simply by evaluating the Mellin transform of the correlation. If the

Mellin transform is evaluated for a certain value of $\bar{\gamma}_k$, then we may evaluate directly the Mellin transform of the one-sided correlation function in $-\gamma_k$ (which is for a value of ρ translated into the fundamental strip by using the technique described in appendix).

As a concluding remark of this section, we may assert that:

- The FSMs are able to reconstitute both power spectral density (see Eq. 16) and the correlation function (see Eq. 27) in the whole domain with exclusion of $\omega = 0$ or $\tau = 0$, respectively. This pathological behavior, due to the discretization in η axis, may be overcome by assuming the value in zero as the value in $\omega = \exp(-b)$.
- The FSMs never diverge provided ρ lies in the fundamental strip of the Mellin transform, then the cutoff value along the imaginary axis may be selected also for a finite value of m , and the truncation of the complex series does not produce divergences as $\omega \rightarrow \infty$ or $\tau \rightarrow \infty$.
- Since $\Lambda_Y(\gamma_k - 1) = \Lambda_Y^*(\gamma_{-k} - 1)$ and $\omega^{-\gamma_k} = (\omega^{-\gamma_{-k}})^*$, then the summation may run from zero up to m with a very simple manipulation.
- For any Mellin transformable function $\lim_{n \rightarrow \pm\infty} \Lambda_Y(\gamma - 1) \rightarrow 0$, this happens since the $\Lambda_Y(\gamma - 1)$ is holomorph into the fundamental strip. This means that the truncation of the summations in Eq. 16 or in Eq. 27 may be properly performed.
- A very important property that allows us to solve fractional differential equations, Fokker-Planck equation, and many other problem is that once the Mellin transform is evaluated for a fixed value of ρ , say ρ_1 , then it may be easily evaluated for any other value of ρ , say ρ_2 , provided ρ_1 and ρ_2 belong to the FS (see “Appendix”).
- Since $\Lambda_Y(\gamma - 1)$ is able to reconstruct both $R_Y(\tau)$ and $S_Y(\omega)$, then it may be stated that $\Lambda_Y(\gamma - 1)$ is another representation that fully describes the process $Y(t)$. It follows that we may now assert that, for a stationary normal process, we have three equivalent

Complex Fractional Moments and Their Use in Earthquake Engineering, Fig. 1 FSM, PSD, and correlation: (a) FSM along the imaginary line $\rho = 0.5$; (b)

PSD (Eq. 31) continuous line, approximated (Eq. 16) dotted line; (c) correlation function (Eq. 32) continuous line, approximated (Eq. 27) dotted line; (d) Fig. 1c in log plot

representations that fully describe the process in statistic sense that are the PSD, the correlation, and the FSM. The first and the second are related to each other by the Fourier Transform operator, while the third representation is related to both the previous ones by the Mellin transform.

Examples

Such an example let $Y(t)$ be a normal zero mean process with a PSD given as

$$S_Y(\omega) = \frac{\alpha \sigma^2}{\pi(\alpha^2 + \omega^2)} \quad (31)$$

The FS for this PSD is $0 < \rho < 2$. The corresponding correlation function is

$$R_Y(\tau) = \frac{1}{2\pi} \sigma^2 \exp(-\alpha|\tau|) \quad (32)$$

The FSM function is

$$\begin{aligned} \Lambda_Y(\gamma - 1) &= 2 \int_0^\infty \frac{\alpha \sigma^2}{\pi(\alpha^2 + \omega^2)} \omega^{\gamma-1} d\omega \\ &= \alpha^{\gamma-1} \sigma^2 \csc(\pi\gamma/2) \end{aligned} \quad (33)$$

Equation 33 may also be obtained from Eq. 32 by using Eq. 30. We evaluate $\Lambda_Y(\gamma - 1)$ in the discrete sequence $\gamma_k = \rho + ik\Delta\eta$. The parameters selected are $\alpha = 0.25$, $\sigma = 0.2$, $\rho = 0.5$, $m = 20$, and $\Delta\eta = 0.5$. The plot of $\Lambda_Y(\gamma - 1)$ along the imaginary axis is reported in Fig. 1a; it may be observed that $\Lambda_Y(\gamma - 1) \rightarrow 0$ at $\eta \rightarrow \pm \infty$. In Fig. 1b, c the PSD and the correlation function given in Eqs. 31 and 32, respectively, are contrasted with those evaluated by Eqs. 16b and 27. In Figure 1d the log plot of the correlation function is contrasted with the results of Eq. 27, showing that the trend at ro is guaranteed. In Fig. 1b the plot of the PSD in the range $-e^{-b} \div e^{-b}$ is plotted, that for the present case ($\Delta\eta = 0.5$) leads to $-1.87 \cdot 10^{-3} \div 1.87 \cdot 10^{-3}$.

Complex Fractional Moments and Their Use in Earthquake Engineering, Fig. 2 FSM and PSD of the Tajimi-Kanai ground acceleration: (a) FSM versus η

($\rho = 0.5$); (b) PSD evaluated by Eq. 34 continuous line, PSD evaluated with Eq. 16 dotted line

From this figure it appears that into the interval $-e^{-\pi/\Delta\eta} \div e^{-\pi/\Delta\eta}$ Eq. 16b shows a divergence phenomenon, but outside the two curves totally overlaps each another. However, the aforementioned problem may be easily overcome by assuming in $\omega = 0$ (or in $\tau = 0$) the value in $e^{-\pi/\Delta\eta}$ so avoiding the pathological behavior in zero. Moreover, the divergence phenomenon in $-e^{-b} \div e^{-b}$ is self-similar in the sense that in the range $-e^{-3b} \div e^{-3b}$, $-e^{-5b} \div e^{-5b} \dots$ the shape of the curve remains the same and then into $-e^{-b} \div e^{-b}$ we have a fractal structure. However, for technical purposes this fact is not influent and is produced by the fact that $\Delta\eta$ is finite. This phenomenon disappears if $\Delta\eta \rightarrow 0$ and $m \rightarrow \infty$ that corresponds to the integral form of the inverse Mellin transform.

As another example the Tajimi-Kanai (1960) PSD given as

$$S_Y(\omega) = 2\pi S_0 \frac{\omega_g^4 + 4\zeta_g^2 \omega_g^2 \omega^2}{(\omega_g^2 - \omega^2)^2 + 4\zeta_g^2 + \omega_g^2 \omega^2} \quad (34)$$

is considered. In Eq. 34 S_0 is the PSD of the white noise at bedrock, and ω_g and ζ_g are the relevant parameters of the ground deposit. In Fig. 2 the PSD given in Eq. 20 is plotted for $S_0 = 1/2\pi$, $\zeta_g = 0.6$, and $\omega_g = 5\pi$. In Fig. 2a the FSM function is plotted along the imaginary axis for $\rho = 0.5$. In Fig. 1b the PSD given in Eq. 20 is

plotted (continuous line) and contrasted with the PSD given in Eq. 16 (dotted line) for $\Delta\eta = 0.5$ and $m = 20$.

From the previous examples, it is evident that the level of accuracy reached by the use of FSM is quite good including the trend at infinity. It is to be emphasized that smaller values of $\Delta\eta$ do not produce sensible variations on both correlation and PSD evaluated by FSM. By contrast the cut-off value $m\Delta\eta = \bar{\eta}$ on the summation in Eq. 16 or in Eq. 27 may produce variations and then has to be appropriately selected. Finally the number of FSM that is necessary to describe the Tajimi-Kanai PSD is very limited; with these complex quantities, all the PSD is restored (with the exception of the value in zero).

Other examples may be found in Cottone and Di Paola (2010) and Di Paola and Pinnola (2012).

Cross-Correlations and Cross-PSD

As the effect of spatial variability and propagation of seismic ground motion on the response of multiply supported structure is considered, the cross-correlation and cross-PSD of the ground acceleration have to be taken into consideration.

Let $Y(x_1, t)$ and $Y(x_2, t)$ the acceleration of the ground at any pairs of different locations x_1 and x_2 . Once x_1 and x_2 are fixed, we have two distinct processes that will be simply indicated as $Y_1(t)$ and $Y_2(t)$. Because the two processes come out

from a propagation of the seismic waves in the medium, they are correlated with each another. Then in order to define the two processes in probabilistic setting, due to the hypothesis of Gaussianity and stationarity, we need of the correlation function matrix

$$\mathbf{R}_Y(\tau) = E[\mathbf{Y}(t)\mathbf{Y}^T(t+\tau)]$$

$$= \begin{bmatrix} R_{Y_1}(\tau) & R_{Y_1Y_2}(\tau) \\ R_{Y_1Y_2}(-\tau) & R_{Y_2}(\tau) \end{bmatrix} \quad (35)$$

where $\mathbf{Y}^T(t) = [Y_1(t)Y_2(t)]$, $R_{Y_j}(\tau)$ is the correlation of Y_j ($j = 1, 2$), and $R_{Y_1Y_2}$ is the cross-correlation between $Y_1(t)$ and $Y_2(t)$. Since $R_{Y_jY_j}(\tau) \in \mathbb{R}$ and $R_{Y_jY_j}(\tau) = R_{Y_jY_j}(-\tau)$, then the Fourier transform of the correlation matrix, namely, the PSD matrix, is given as

$$\mathbf{S}_Y(\omega) = \begin{bmatrix} S_{Y_1}(\omega) & S_{Y_1Y_2}(\omega) \\ S_{Y_1Y_2}^*(\omega) & S_{Y_2}(\omega) \end{bmatrix} \quad (36)$$

where $S_{Y_1Y_2}(\omega)$ is the cross-PSD of the two processes $Y_1(t)$ and $Y_2(t)$. The PSD matrix (36) is Hermitian and $S_{Y_1Y_2}(\omega)$ is a complex function whose real part is even in ω and the imaginary part is odd. Under the far-field assumption, usually it is assumed that $S_{Y_1Y_2}(\omega) = S_{Y_2Y_1}(\omega) = S_Y(\omega)$ and $S_{Y_1Y_2}(\omega)$ is usually defined as (Harichandran and Vanmarcke 1986; Zerva 1991)

$$S_{Y_1Y_2}(\omega) = S_Y(\omega) |\rho^{(1,2)}(\omega, |\xi|)| \exp(i\omega\xi/v) \quad (37)$$

where $\rho^{(1,2)}(\omega, \xi)$ is the so-called coherence function depending of the radian frequency ω and of the distance $\xi = x_2 - x_1$ between the different points as well. The coherence function is even $\rho^{(1,2)}(\omega, |\xi|) = \rho^{(1,2)}(-\omega, |\xi|)$ and is usually assumed to be exponentially decaying with $|\xi|$. The various parameters are selected in order to fit experimental data. Moreover the factor $\exp(i\omega\xi/v)$, where v is the velocity of the traveling waves in the medium, takes into account for the retardation time of the waves from two different points. In any case, whatever the coherence function is selected, the

representation of the cross-PSD with the FSM requests the definition of the real and imaginary part of Eq. 37:

$$\Re[S_{Y_1Y_2}(\omega)] = S_Y(\omega) |\rho^{(1,2)}(\omega, |\xi|)| \cos \frac{\omega\xi}{v} \quad (38a)$$

$$\Im[S_{Y_1Y_2}(\omega)] = S_Y(\omega) |\rho^{(1,2)}(\omega, |\xi|)| \sin \frac{\omega\xi}{v} \quad (38b)$$

where $\Re[\cdot]$ and $\Im[\cdot]$ are the real and imaginary part of the term in parentheses. The Mellin transform borns for functions that are defined in the range $0 \div \infty$. For $S_{Y_j}(\omega)$ Eq. 16b restores the PSD in terms of FSM. For the cross-PSD, we may consider the real and the imaginary part separately. By taking into account Eq. 16b for the real part given in Eq. 38a, because it is an even function like $S_Y(\omega)$, we may write

$$\Re[S_{Y_1Y_2}(\omega)] = \frac{1}{4b} \sum_{k=-m}^m A_{Y_1Y_2}^{\Re}(\gamma_k - 1) |\omega|^{-\gamma_k} \quad (39)$$

Regarding the imaginary part since $\Im[S_{Y_1Y_2}(\omega)] = -\Im[S_{Y_1Y_2}(-\omega)]$, once the imaginary part of $S_{Y_1Y_2}(\omega)$ is defined in the positive frequency range, it may be immediately evaluated also in the negative one, that is,

$$\Im[S_{Y_1Y_2}(\omega)] = \frac{1}{4b} \text{sgn}(\omega) \sum_{k=-m}^m A_{Y_1Y_2}^{\Im}(\gamma_k - 1) \text{sgn}(\omega) |\omega|^{-\gamma_k} \quad (40)$$

where $\text{sgn}(\cdot)$ is the signum function.

In Eqs. 39 and 40, the FSM $A_{Y_1Y_2}^{\Re}(\gamma - 1)$, $A_{Y_1Y_2}^{\Im}(\gamma - 1)$ are given as

$$A_{Y_1Y_2}^{\Re}(\gamma - 1) = 2 \int_0^{\infty} \Re[S_{Y_1Y_2}(\omega)] \omega^{\gamma-1} d\omega \quad (41)$$

$$A_{Y_1Y_2}^{\Im}(\gamma - 1) = 2 \int_0^{\infty} \Im[S_{Y_1Y_2}(\omega)] \omega^{\gamma-1} d\omega \quad (42)$$

It follows that the cross-PSD is given as

$$S_{Y_1 Y_2}(\omega) = \frac{1}{4b} \sum_{k=-m}^m \left[A_{Y_1 Y_2}^{\Re}(\gamma_k - 1) + i \operatorname{sgn}(\omega) A_{Y_1 Y_2}^{\Im}(\gamma_k - 1) \right] |\omega|^{-\gamma_k} \quad (43)$$

Inverse Fourier transform gives the cross-correlation function in the form

$$R_{Y_1 Y_2}(\tau) = \frac{1}{4\pi b} \sum_{k=-m}^m A_{Y_1 Y_2}^{\Re}(\gamma_k - 1) v_c(1 - \gamma_k) + \operatorname{sgn}(\tau) A_{Y_1 Y_2}^{\Im}(\gamma_k - 1) v_s(1 - \gamma_k) |\tau|^{\gamma_k - 1} \quad (44)$$

where $v_s(1 - \gamma_k) = \Gamma(1 - \gamma_k) \sin[(1 - \gamma_k)\pi/2]$. As in the case of autocorrelation also for the cross-correlation, the FSM may be directly evaluated by starting from $R_{Y_1 Y_2}(\tau)$ instead of $S_{Y_1 Y_2}(\omega)$. In order to do this, we may decompose $R_{Y_1 Y_2}(\tau)$ in an even and an odd function

$$R_{Y_1 Y_2}(\tau) = R_{Y_1 Y_2}^{ev}(\tau) + R_{Y_1 Y_2}^{od}(\tau) \quad (45)$$

where

$$R_{Y_1 Y_2}^{ev}(\tau) = \frac{1}{2} (R_{Y_1 Y_2}(\tau) + R_{Y_1 Y_2}(-\tau)) \quad (46a)$$

$$R_{Y_1 Y_2}^{od}(\tau) = \frac{1}{2} (R_{Y_1 Y_2}(\tau) - R_{Y_1 Y_2}(-\tau)) \quad (46b)$$

Now we may define

$$\begin{aligned} C_{Y_1 Y_2}^{ev}(\tau) &= 2U(\tau) R_{Y_1 Y_2}^{ev}(\tau); \\ C_{Y_1 Y_2}^{od}(\tau) &= 2U(\tau) R_{Y_1 Y_2}^{od}(\tau) \end{aligned} \quad (47)$$

whose Mellin transform gives

$$\begin{aligned} \mathcal{M} \left\{ C_{Y_1 Y_2}^{od}(\tau), \bar{\gamma} \right\} &= \int_0^{\infty} C_{Y_1 Y_2}^{od}(\tau) \tau^{\bar{\gamma}-1} d\tau \\ &= \Theta_{Y_1 Y_2}^{od}(\bar{\gamma} - 1) \end{aligned} \quad (48)$$

then discrete inverse Mellin transform gives

$$C_{Y_1 Y_2}^{ev}(\tau) = \frac{1}{4\pi b} \sum_{k=-m}^m \Theta_{Y_1 Y_2}^{ev}(\bar{\gamma}_k - 1) |\tau|^{-\bar{\gamma}_k}; \quad (49a)$$

$$C_{Y_1 Y_2}^{od}(\tau) = \frac{\operatorname{sgn}(\tau)}{4\pi b} \sum_{k=-m}^m \Theta_{Y_1 Y_2}^{od}(\bar{\gamma}_k - 1) |\tau|^{-\bar{\gamma}_k} \quad (49b)$$

The cross-spectral moments of the correlation function may be rewritten in terms of cross-FSM $\Lambda_{Y_1 Y_2}^{ev}(\gamma_k - 1)$ and $\Lambda_{Y_1 Y_2}^{od}(\gamma_k - 1)$, respectively, in the form

$$\begin{aligned} \Lambda_{Y_1 Y_2}^{ev}(\gamma_k - 1) &= 2\Theta_{Y_1 Y_2}^{ev}(-\gamma_k) v_c(\gamma_k); \\ \Lambda_{Y_1 Y_2}^{od}(\gamma_k - 1) &= 2\Theta_{Y_1 Y_2}^{od}(-\gamma_k) v_s(\gamma_k) \end{aligned} \quad (50)$$

Filter Equation

In order to find the filter equation by using FSM, fractional calculus, and related concepts, we suppose that the ground acceleration $Y(t)$ is a stationary normal stochastic process characterized by $S_Y(\omega)$. We now suppose that $Y(t)$ is the output of a linear differential equation

$$\mathcal{N}[Y(t)] = W(t) \quad (51)$$

or by using its inverse, we get

$$Y(t) = \mathcal{M}[W(t)] \quad (52)$$

where $\mathcal{N}[\cdot]$ and $\mathcal{M}[\cdot]$ are a priori unknown linear operator and $W(t)$ is a normal white noise process $E[W(t)W(t + \tau)] = 2\pi S_0 \delta(\tau)$. The operator $\mathcal{N}[\cdot]$ or $\mathcal{M}[\cdot]$ has to be selected in such a way that the PSD of the output of Eq. 51 coalesces with the target PSD $S_Y(\omega)$, that is, given as

$$S_Y(\omega) = |H(\omega)|^2 S_0 \quad (53)$$

where $H(\omega)$ is the (unknown) transfer function of the linear operator $\mathcal{N}[\cdot]$. Without loss of generality, we assume a unitary S_0 (in L^2/T^3). Unfortunately from Eq. 53 the only information on the

stochastic process $Y(t)$ is the PSD, and from this unique information, the (complex) function $H(\omega)$ may not be reconstructed. However because we are interested to represent the stationary process $Y(t)$, then we may assume that

$$H(\omega) = \sqrt{S_Y(\omega)} \quad (54)$$

With this choice the corresponding impulse response function of $\mathcal{N}[\cdot]$ is symmetric in time domain, and then it violates the causality condition. Even though the causality condition is violated, in the frame of stationary processes, this does not produce any problem since the output of Eq. 51 remains a normal strictly stationary process with PSD $S_Y(\omega)$ that is the target one.

As the impulse response function is assumed as in Eq. 54, we may evaluate the FSM of $\sqrt{S_Y(\omega)} = H(\omega)$

$$\Lambda_H(\gamma - 1) = \int_0^\infty 2\sqrt{S_Y(\omega)}\omega^{\gamma-1}d\omega \quad (55)$$

and the inverse Mellin transform gives

$$\sqrt{S_Y(\omega)} = H(\omega) = \frac{1}{4b} \sum_{k=-m}^m \Lambda_H(\gamma_k - 1) |\omega|^{-\gamma_k} \quad (56)$$

By denoting the impulse response function corresponding to the transfer function $H(\omega) = \sqrt{S_Y(\omega)}$ as $h(t)$, an inverse Fourier transform of Eq. 56 gives

$$h(t) = \frac{1}{4\pi b} \sum_{k=-m}^m v_c(1 - \gamma_k) \Lambda_H(1 - \gamma_k) |t|^{\gamma_k-1} \quad (57)$$

This equation has been obtained observing that $h(t)$ is the inverse Fourier transform of $H(\omega)$, and then it may be treated as the case of correlation function of a PSD defined as $\sqrt{S_Y(\omega)}$ (see Eq. 34).

Once the impulse response is obtained, then the filter equation is readily found as

$$Y(t) = \frac{1}{4\pi b} \sum_{k=-m}^m v_c(1 - \gamma_k) \Lambda_H(1 - \gamma_k) \int_{-\infty}^{\infty} |t - \tau|^{1-\gamma_k} W(\tau) d\tau = \frac{1}{4b} \sum_{k=-m}^m \Lambda_H(1 - \gamma_k) (I^{\gamma_k} W)(t) \quad (58)$$

that is the discrete filter equation. An exact representation is given in the form

$$Y(t) = \frac{1}{4\pi i} \int_{\rho-i\infty}^{\rho+i\infty} \Lambda_H(1 - \gamma) (I^{\gamma} W)(t) d\gamma \quad (59)$$

Some comments are necessary to highlight the peculiar aspect of the filter equation in Eq. 58 or 59:

- In order to find the process $Y(t)$, we need of the quantities $\Lambda_H(1 - \gamma_k)$ that play the role of amplification factor of the Riesz fractional derivatives of the white noise $W(t)$. Even though $W(t)$ is nowhere differentiable, the fractional derivative exists since the kernel of the Riesz integral smooths the singularities (see West et al. 2003); see also Chechkin and Gonchar (2001), Grigoriu (2007), and Ortigueira and Batista (2008)).
- Equation 58 looks like a moving-average model, as in fact the actual value of $Y(t)$ depends of the entire past and future history of $W(t)$ as well.
- The value of ρ selected for the definition of the filter equation influences both $\Lambda_H(1 - \gamma_k)$ and $(I^{\gamma_k} W)(t)$, but the result is not affected by the value of the ρ selected provided it belongs to the FS of the Mellin transform.

In Fig. 3a the impulse response function evaluated by Eq. 57 with the PSD of the earthquake acceleration modeled as the Tajimi-Kanai filter given in Eq. 34 with $S_0 = 1/2\pi$, $\omega_g = 5\pi$, $\zeta_g = 0.6$ is plotted. Results are compared with the inverse Fourier transform of $\sqrt{S_Y(\omega)}$. In Fig. 3b the transfer function, obtained as $\sqrt{S_Y(\omega)}$, with $\sqrt{S_Y(\omega)}$, the Tajimi-Kanai PSD is compared with the results obtained by Eq. 56.

Complex Fractional Moments and Their Use in Earthquake Engineering, Fig. 3 $H(\omega)$ and $h(t)$ of the Tajimi-Kanai ground acceleration: (a) $h(t)$ evaluated as inverse Fourier transform of Eq. 54 (continuous line), $h(t)$

evaluated with Eq. 57 (dotted line); (b) $H(\omega)$ evaluated with Eq. 54 (continuous line), $H(\omega)$ evaluated with Eq. 56 (dotted line)

For more details on the filter equations and generation of sample function, see Cottone et al. (2010).

Summary

Fractional calculus opens new perspectives for solving problems that with the classical calculus may not be solved. The initial effort to understand the rules is fully rewarded from the elegance and the unbelievable accuracy obtained.

In this entry only two problems have been presented: representation of the power spectral density (PSD) and correlation by means of complex fractional moments and filter equations. Regarding the first problem, it has been shown that both PSD and correlation may be represented by the so-called fractional spectral moments (FSMs). The latter are the extension of the classical spectral moments introduced by Vanmarcke (1972) to complex order. The appealing in using these FSM is that they are able to reconstruct both PSD and correlation. As a result, it may be stated that FSM function is another equivalent representation of PSD and correlation. Moreover it has been shown that with a limited number of informations (few FSM), the whole PSD and correlation may be restored, including the trend at infinity. Extension to multivariate seismic process has been also provided in both frequency

and time domain. By using FSM also the filter equations have been found. It is shown that both impulse response function and its Fourier transform, namely, the transfer function of the filter, may be found by evaluating the FSM of the squared root of the target PSD.

By using the same concepts, a very large number of other problems may be solved. Such an example the probability density function of a random variable may be obtained with the same technique here used for representing cross-correlations in terms of FSMs. It follows that Fokker-Planck equation, Kolmogorov-Feller equation, Einstein-Smoluchowski equation, and path integral solution (Cottone et al. 2008) may be solved in terms of FSM. Moreover, wavelet transform and classical or fractional differential equations may be easily solved by using fractional calculus and Mellin transform in complex domain.

Acknowledgments The author is indebted to the Ph.D. student Gioacchino Alotta for the help in preparing the numerical applications.

Appendix

In this Appendix it is shown that once the Mellin transform of a given function is evaluated for a certain value ρ_1 (into the fundamental strip), the Mellin transform of the function may be

evaluated for any other value ρ_2 (into the FS) as a linear combination of the fractional spectral moments of the function evaluated in ρ_1 . This fact is very important in order to solve a lot of problems like solution of fractional differential equation, Fokker-Planck equation, and Einstein-Smoluchowski equation and also to evaluate FSM for different value of ρ ; see Eq. 26. Results of this appendix have been found by the author (Di Paola 2014; Di Matteo et al. 2014) for solving Fokker-Planck equation and Kolmogorov-Feller equation.

We denote as $f_{\mathcal{M}}(\gamma^{(1)} - 1)$ the Mellin transform of the function $f(t)$ which evaluates for $\rho = \rho_1$, that is,

$$f_{\mathcal{M}}(\gamma^{(1)} - 1) = \mathcal{M}\{f(t); \gamma\} = \int_0^{\infty} f(t) t^{\gamma^{(1)}-1} dt; \quad (60)$$

$$\gamma^{(1)} = \rho_1 + i\eta$$

Inverse Mellin transform operator returns $f(t)$ in the form

$$f(t) \simeq \frac{\Delta\eta}{2\pi} \sum_{k=-m}^m f_{\mathcal{M}}(\gamma_k^{(1)} - 1) t^{-\gamma_k^{(1)}} \quad (61)$$

Since Eqs. 60 and 61 remain valid also for $\rho = \rho_2$, we may write

$$\begin{aligned} & \frac{\Delta\eta}{2\pi} \sum_{k=-m}^m f_{\mathcal{M}}(\gamma_k^{(1)} - 1) t^{-\gamma_k^{(1)}} \\ & \simeq \frac{\Delta\eta}{2\pi} \sum_{k=-m}^m f_{\mathcal{M}}(\gamma_k^{(2)} - 1) t^{-\gamma_k^{(2)}} \end{aligned} \quad (62)$$

where $\gamma^{(2)} = \rho_2 + i\eta$. By multiplying both sides of Eq. 62 for $t^{-1/2}$ and remembering that $\gamma^{(j)} = \rho^{(j)} + i\eta$ ($j = 1, 2$), we obtain

$$\begin{aligned} & t^{-1/2} \sum_{k=-m}^m f_{\mathcal{M}}(\gamma_k^{(1)} - 1) e^{-ik\frac{\pi}{b}\text{Int}} \simeq t^{-(\Delta\rho+1/2)} \\ & \sum_{k=-m}^m f_{\mathcal{M}}(\gamma_k^{(2)} - 1) e^{-ik\frac{\pi}{b}\text{Int}}; \quad x > 0 \end{aligned} \quad (63)$$

where $\Delta\rho = \rho_2 - \rho_1$. It is to be remarked that Eq. 63 strictly holds for $t > 0$ because in zero singularities appear. Now we want to evaluate coefficients $f_{\mathcal{M}}(\gamma_k^{(2)} - 1)$ from the knowledge of $f_{\mathcal{M}}(\gamma_k^{(1)} - 1)$. Because Eq. 61 is an approximation, we require that Eq. 63 holds true in a weak sense in the interval $t_1 > 0, t_2 \gg 0$:

$$\begin{aligned} & \int_{t_1}^{t_2} \frac{1}{t} \left\{ \left[\sum_{s=-m}^m f_{\mathcal{M}}(\gamma_s^{(1)} - 1) e^{-is\frac{\pi}{b}\text{Int}} - t^{-(\Delta\rho)} \sum_{k=-m}^m f_{\mathcal{M}}(\gamma_k^{(2)} - 1) e^{-ik\frac{\pi}{b}\text{Int}} \right] \times [C.C.] \right\} dt \\ & = \min(f_{\mathcal{M}}(\gamma_k^{(2)} - 1)) \end{aligned} \quad (64)$$

where $C.C.$ stands for complex conjugate. It is convenient to make a change of variables

$$\xi = \text{Int}, d\xi = \frac{dt}{t}; \xi_j = \text{Int}_j, j = 1, 2 \quad (65)$$

Moreover, a good choice of t_1 and t_2 in Eq. 64 is $t_1 = e^{-b} = e^{-\frac{\pi}{\Delta\eta}}$, $t_2 = e^b = e^{\frac{\pi}{\Delta\eta}}$. With this

choice two goals are achieved. First the interval $e^{-b} \div e^b$ is very wide for the usual values of $\Delta\eta$ ($\Delta\eta = 0.25 \div 0.5$). As in fact in the worst case ($\Delta\eta = 0.5$) $e^{-b} = 1.87 \cdot 10^{-3}$, $e^b = 5.35 \cdot 10^2$; second in the ξ domain the extremes of the integral (64) become $-b \div b$ and in this interval $\exp(-i\frac{\pi}{b}s\xi)$ are orthogonal.

Then Eq. 64 in ξ domain is rewritten as

$$\int_{-b}^b \left\{ \left[\sum_{s=-m}^m f_{\mathcal{M}}(\gamma_s^{(1)} - 1) e^{-is\frac{\pi}{b}\xi} - e^{-\Delta\rho\xi} \sum_{k=-m}^m f_{\mathcal{M}}(\gamma_k^{(2)} - 1) e^{-ik\frac{\pi}{b}\xi} \right] \times [C.C.] \right\} d\xi$$

$$= \min(f_{\mathcal{M}}(\gamma_s^{(1)} - 1)) \quad (66)$$

Due to the orthogonality conditions in $-b \div b$ after minimization, we obtain

$$2bf_{\mathcal{M}}(\gamma_s^{(1)} - 1) = \sum_{k=-m}^m f_{\mathcal{M}}(\gamma_k^{(2)} - 1) a_{ks}(\Delta\rho) \quad (67)$$

where

$$a_{ks}(\Delta\rho) = \int_{-b}^b e^{-\Delta\rho\xi} e^{-i(k-s)\frac{\pi}{b}\xi} d\xi$$

$$= \frac{2b \sin[\pi(k-s) - ib\Delta\rho]}{\pi(k-s) - ib\Delta\rho} \quad (68)$$

Inspection of Eqs. 67 and 68 reveals that the Mellin transform $f_{\mathcal{M}}(\gamma_s^{(1)} - 1)$ is related to the Mellin transform $f_{\mathcal{M}}(\gamma_k^{(2)} - 1)$ as a linear combination of $f_{\mathcal{M}}(\gamma_k^{(1)} - 1)$ with the coefficients in Eq. 68.

Synonyms

Conditional mean spectrum; Hazard-consistent ground motion selection; Response spectrum; Scenario spectrum; Spectral shape

Introduction

The conditional spectrum (CS) is a response spectrum that specifies the probability distribution of spectral accelerations, S_a , over a range of

periods of vibration, T_i , conditioned on spectral acceleration at a conditioning period, T^* , of interest. The conditional spectrum utilizes the correlations between spectral accelerations at different periods (e.g., Baker and Jayaram 2008) to compute the expected (logarithmic mean) response spectrum (Baker and Cornell 2006; Baker 2011) and additionally account for the variability (variance) of the response spectra (Jayaram et al. 2011; Lin et al. 2013a). Assuming the distribution of logarithmic spectral accelerations is multivariate normal (Jayaram and Baker 2008), then the first two moments (i.e., the means, standard deviations, and correlations) fully describe the conditional spectrum. The CS provides the link between seismic hazard and structural response, the first two elements of performance-based earthquake engineering (PBEE). To maintain consistency with probabilistic seismic hazard analysis (PSHA), the computation of the CS is refined by incorporating multiple causal earthquakes and ground motion prediction models (GMPMs, also known as ground motion prediction equations, attenuation relationships) (Lin et al. 2013a). The CS can be used as a target response spectrum for site- and structure-specific ground motion selection (e.g., Lin et al. 2013b, c).

Baker and Cornell (2006) and Baker (2011) described the “conditional spectrum” as the “conditional mean spectrum” (CMS) with an emphasis on the mean spectrum and its associated ground motion selection where the best ground motion candidates have response spectra as close to the CMS as possible. Bradley (2010) extended the concept of the CMS to ground motion parameters other than response spectra and referred the resulting distribution as a “generalized conditional intensity measure” (GCIM). Bradley (2012) also developed an algorithm to select ground motions based on the GCIM. Abrahamson and Al Atik (2010) coined the term “conditional spectrum”, but represented the CS distribution directly by realizations of the CS rather than an analytical distribution. Wang (2011) developed a ground motion selection algorithm that captures response spectrum characteristics and variability of scenario earthquakes. Gulercce and Abrahamson (2011) extended the CS concept to vertical ground

Conditional Spectra, Fig. 1 Response spectra of ground motions selected and scaled with (a) conditional spectrum, (b) conditional mean spectrum, and (c) uniform

hazard spectrum as target spectra for $S_a(2.6\text{ s})$ associated with 2 % in 50 years probability of exceedance for an illustrative structure in Palo Alto, California, USA

motions. Jayaram et al. (2011) developed a computationally efficient algorithm to select ground motions that match the conditional mean and variance of the response spectrum.

Lin et al. (2013a) for the first time used the term “conditional spectrum” which was used to represent an analytical distribution of response spectra in the manner described here. The CS builds upon the CMS (which focuses on the mean) and includes a measure of the variance in addition to the mean. Figure 1a depicts the analytical distribution of the conditional spectrum with conditional mean spectrum as the thick solid line as well as conditional mean $\pm$ conditional standard deviation as the thick dashed lines. Lin et al. (2013b, c) utilized the conditional spectrum to select ground motions for nonlinear dynamic analysis (also known as response history

analysis) in risk-based and intensity-based assessments respectively. Intensity-based assessment estimates structural response given ground motions with a specified intensity level. Risk-based assessment (also known as PEER integral, drift hazard, time-based assessment, and probabilistic seismic demand analysis) estimates the mean annual rate of exceeding a specified structural response amplitude and can be obtained by integrating intensity-based assessment results at various intensity levels with the associated seismic hazard curve. As illustrated in Fig. 1a, the thin lines represent response spectra from individual ground motion records selected to match the mean and variance of the CS (thick solid and dashed lines) for a specified intensity level, i.e., spectral acceleration at the period of 2.6 s (“pinched” conditioning period) associated with

2 % in 50 years probability of exceedance in Palo Alto, California, USA.

The consideration of the variability in the CS is important to capture the full distribution of the target S_a and its subsequent structural response analysis based on a target response spectrum. Lin et al. (2013c) compared the conditional spectrum (Fig. 1a) to such alternative response spectra as the conditional mean spectrum (Fig. 1b) and the uniform hazard spectrum (UHS) (Fig. 1c); the issue of the choice of the conditioning period was also discussed. The CMS (thick solid line) and UHS (thick dash-dot line) are superimposed on the CS as reference spectra in Fig. 1a. Figure 1b depicts the CMS as the target response spectrum, whereas the thin lines represent individual record response spectra selected to match the mean. Figure 1c illustrates the UHS as the target response spectrum and individual record spectra selected to match the UHS. Unlike the UHS (Fig. 1c), the CS (Fig. 1a) has a lower mean at periods away from the conditioning period. Unlike the CMS (Fig. 1b), the CS additionally considers the spectral uncertainty about the mean.

Background

Performance-based earthquake engineering quantifies the seismic hazard, predicts the structural response, estimates the damage to building elements (structural, non-structural, and content), in order to assess resulting losses in terms of dollars, downtime, and deaths (e.g., Cornell and Krawinkler 2000). One key input to seismic design and analysis of structures is earthquake ground motion. Ground motion selection determines ground motion input for a structure at a specific site for nonlinear dynamic analysis. Ground motion selection provides a significant basis for conclusions regarding structural safety, since ground motion uncertainty contributes considerably to uncertainty in structural analysis output.

The source of ground motion inputs can come from (1) simulations, either physics-based (physics-based ground motion simulation),

stochastic (stochastic ground motion simulation), or hybrid; (2) spectral matching; (3) selection and scaling of recorded ground motions from ground motion databases (selection of ground motions for response history analysis). Physics-based simulations attempt to depict the physical phenomenon of earthquake fault rupture and wave propagation using analytical models while stochastic simulations rely heavily on empirical calibration with an attempt to generate ground motions using fewer random variables. Hybrid simulations, on the other hand, combine the two by utilizing physics-based simulations for low-frequency components and stochastic simulations for high-frequency components. A semi-artificial ground motion modification technique is spectral matching that changes the frequency content of the response spectra to be compatible with the target. Another modification technique is selection and scaling of ground motions (e.g., Katsanos et al. 2010) that involves selecting recorded ground motions from ground motion databases and applying amplitude scaling to match the target.

To ensure the proper quantification of ground motion uncertainty, it is important to link ground motion selection to probabilistic seismic hazard analysis (e.g., Cornell 1968). PSHA (probabilistic seismic hazard models) is commonly used in structural dynamic analysis and geotechnical earthquake engineering to identify the ground motion hazard for which structural and geotechnical systems are analyzed and designed. PSHA accounts for the aleatory uncertainties (which are inherently random) of causal earthquakes with different magnitudes and distances with predictions of resulting ground motion intensity in order to compute seismic hazard at a site. PSHA also incorporates epistemic uncertainties (which are due to limited knowledge) in ground motion predictions, by considering multiple ground motion prediction models using a logic tree that also includes seismic source models.

Ground motion selection is often associated with a target response spectrum. For instance, the target response spectrum in current building codes (e.g., ASCE 2010) is based on the uniform

Conditional Spectra, Fig. 2 (a) Conditional mean spectra at $T^* = 2.6$ s at various intensity levels (from 50 % in 30 years to 1 % in 200 years) and (b) conditional mean

spectra at various conditioning periods (compared to uniform hazard spectrum) at the 2 % in 50-year intensity level

hazard spectrum, which assumes equal probabilities of exceedance of spectral accelerations at all periods. However, no single ground motion is likely to produce a response spectrum as high as that of the UHS over a wide range of periods (e.g., Naeim and Lew 1995). The conditional mean spectrum utilizes the correlations of S_a across periods to more realistically compute the expected S_a values at all periods given a target S_a value at a period of interest (e.g., Baker and Cornell 2006). The conditional spectrum quantifies the conditional distribution (mean and variance) of S_a at all periods given S_a at a period of interest (e.g., Lin et al. 2013a). The spectral shapes of conditional mean spectra (mean of conditional spectra) change with amplitudes (Fig. 2a). Uniform hazard spectrum is the envelope of conditional mean spectra at various periods (Fig. 2b).

The target response spectrum used when selecting ground motions has an impact on the distribution of structural responses from resulting nonlinear dynamic analysis (e.g., Jayaram et al. 2011; Lin et al. 2013c). Matching target response variance (in the CS compared to the CMS) increases the dispersion of structural responses, thereby affecting the distribution of structural responses and consequently the damage state and loss estimation computations in performance-based earthquake engineering. The increase in the

dispersion leads to higher and lower extremes of structural responses and the associated damage states and losses. The increased dispersion can also lead to a larger probability of structural collapse. Incorporating the variability in the CS has significant implications for applications where the dispersion of the responses is an important consideration.

Basic Computation

The basic computation of the conditional spectrum requires (1) input earthquake parameters such as magnitude and distance (similar to those required by a GMPM), (2) specification of a conditioning period, (3) a ground motion prediction model to estimate mean and standard deviation of logarithmic spectral acceleration, and (4) a correlation model of spectral accelerations across periods. The computation procedure is outlined as follows:

- (a) Obtain input earthquake parameters: Obtain the target spectral acceleration at the conditioning period T^* , $S_a(T^*)$, from PSHA, and its associated mean causal earthquake magnitude (M), distance (R), and other parameters (if available) such as rupture mechanism and site condition (θ), from deaggregation (e.g., McGuire 1995).

- (b) Compute mean and standard deviation of $\ln Sa(T_i)$: Use a GMPM (e.g., Abrahamson et al. 2008) to compute the logarithmic mean and standard deviation of Sa at all periods T_i , denoted as $\mu_{\ln Sa}(M, R, \theta, T_i)$ and $\sigma_{\ln Sa}(M, \theta, T_i)$.
- (c) Compute epsilon, $\epsilon(T_i)$: For any $Sa(T_i)$, compute $\epsilon(T_i)$, the number of standard deviations by which $\ln Sa(T_i)$ differs from the mean spectral ordinate predicted by a given GMPM, $\mu_{\ln Sa}(M, R, \theta, T_i)$, at T_i

$$\epsilon(T_i) = \frac{\ln Sa(T_i) - \mu_{\ln Sa}(M, R, \theta, T_i)}{\sigma_{\ln Sa}(M, \theta, T_i)} \quad (1)$$

The target $\epsilon(T^*)$ can also be computed using this equation. Spectral shape is characterized by ϵ .

- (d) Compute conditional mean $\mu_{\ln Sa(T_i)|\ln Sa(T^*)}$: Using a correlation model (e.g., Baker and Jayaram 2008) that specifies the correlation coefficient between pairs of epsilon values at two periods, $\rho(\epsilon(T_i), \epsilon(T^*))$ (hereinafter referred to as $\rho(T_i, T^*)$), the conditional mean logarithmic spectral acceleration at other periods T_i , $\mu_{\ln Sa(T_i)|\ln Sa(T^*)}$ is computed

$$\begin{aligned} \mu_{\ln Sa(T_i)|\ln Sa(T^*)} &= \mu_{\ln Sa}(M, R, \theta, T_i) \\ &+ \rho(T_i, T^*) \sigma_{\ln Sa}(M, \theta, T_i) \end{aligned} \quad (2)$$

The spectrum defined by $\mu_{\ln Sa(T_i)|\ln Sa(T^*)}$ is termed the “conditional mean spectrum”, as it specifies the mean values of $\ln Sa(T_i)$ conditional on the value of $\ln Sa(T^*)$. Assuming Sa is lognormally distributed, the exponentials of $\mu_{\ln Sa}$ are equivalent to the median values of Sa .

- (e) Compute conditional standard deviation $\sigma_{\ln Sa(T_i)|\ln Sa(T^*)}$: The standard deviation of logarithmic spectral acceleration at period T_i conditioned on the value of $\ln Sa(T^*)$ is

$$\sigma_{\ln Sa(T_i)|\ln Sa(T^*)} = \sigma_{\ln Sa}(M, \theta, T_i) \sqrt{1 - \rho^2(T_i, T^*)} \quad (3)$$

The conditional standard deviation $\sigma_{\ln Sa(T_i)|\ln Sa(T^*)}$, when combined with the

conditional mean value $\mu_{\ln Sa(T_i)|\ln Sa(T^*)}$, specifies a complete distribution of logarithmic spectral acceleration values at all periods (where the distribution at a given period is Gaussian, as justified by Jayaram and Baker 2008). The resulting spectrum distribution is termed the “conditional spectrum”, to be distinguished from the CMS that does not consider the variability.

Deaggregation of Ground Motion Prediction Models

Probabilistic seismic hazard deaggregation of GMPMs links the computation of a target spectrum (for ground motion selection) to the total hazard prediction (from PSHA). Computation of a target spectrum requires deaggregation (via Bayes’ rule) to identify the causal ground motion parameters, along with the predictions from multiple GMPMs. Hazard-consistent ground motion selection incorporates the aleatory uncertainties from earthquake scenarios and the epistemic uncertainties from multiple GMPMs, through deaggregation of GMPMs (Lin and Baker 2011).

This GMPM deaggregation is consistent with the probabilistic treatment of the magnitude and distance random variables in traditional PSHA. The deaggregation of GMPMs provides additional insights into which GMPM contributes most to prediction of Sa values of interest. To match the contribution of each GMPM to its associated ground motion parameters, separate deaggregation of earthquake parameters for each GMPM is also performed. First, seismic hazard is estimated using PSHA that incorporates multiple GMPMs. Next, the relative contributions of events and GMPMs to the hazard prediction are identified using the refined deaggregation procedures.

The deaggregation of GMPMs is performed as an intermediate step to develop a refined mean and, more importantly, a refined standard deviation of the CS. This can also be used to develop, in general, any new target response spectrum that is consistent with PSHA. The side product of this computation is the deaggregation (posterior) weights of GMPMs, instead of the

Conditional Spectra, Fig. 3 (a) Conditional means and (b) conditional standard deviations of the CS computed using Methods 2–4 for $Sa(0.2\text{ s})$ with 10 % probability of exceedance in 50 years at Bissell

logic-tree (prior) weights. This methodology for deaggregation of prediction models can also be immediately applicable to other procedures which require multiple prediction models in an earlier stage of total prediction and a later stage of new target computation.

Refined Computational Methods

Approximate and exact implementations of CS computations are outlined and used for example calculations at Stanford, Bissell, and Seattle (Lin et al. 2013a). Figure 3 illustrates CS mean and standard deviation computational methods using multiple GMPMs at Bissell. Exact CS mean and standard deviation calculations (Method 4) can incorporate multiple GMPMs and causal earthquake M/R combinations. Varying levels of approximations are also considered, that replace multiple M/R combinations with the mean M/R from deaggregation (Methods 1–3), and either consider only a single GMPM (Method 1) or perform an approximate weighting of several GMPMs (Methods 2–3). Methods 1–2 utilize the overall mean M/R , whereas Method 2 considers multiple GMPMs with logic-tree weights. The deaggregation of GMPMs provides GMPM-specific mean M/R and GMPM deaggregation weights, both of which are incorporated in Method 3. The most accurate computation,

Method 4, accounts for the contribution that each GMPM and each earthquake M/R makes to the seismic hazard (Fig. 3). Subscript k denotes that the calculations are based on a specific GMPM indexed by k , whereas subscript j denotes that the parameters such as M/R are associated with a specific earthquake indexed by j . For each GMPM k and causal earthquake combination M_j/R_j , mean and standard deviation of the CS can be obtained (using Eqs. 12 and 13, respectively) that are then combined with corresponding deaggregation weights, $p_{j,k}^d$ (Eqs. 14 and 15). The weight for model k is denoted as p_k^l where the superscript l refers to logic-tree; similarly, the superscript d in p_k^d and $p_{j,k}^d$ refers to deaggregation.

Method 1: Approximate CS using mean M/R and a single GMPM (basic computation)

$$\begin{aligned} \mu_{\ln Sa, k(T_i) | \ln Sa(T^*)} &\approx \mu_{\ln Sa, k}(\bar{M}, \bar{R}, \bar{\theta}, T_i) \\ &+ \rho(T_i, T^*) \sigma_{\ln Sa, k}(\bar{M}, \bar{\theta}, T_i) \bar{\epsilon}(T^*) \end{aligned} \quad (4)$$

$$\sigma_{\ln Sa, k(T_i) | \ln Sa(T^*)} \approx \sigma_{\ln Sa, k}(\bar{M}, \bar{\theta}, T_i) \sqrt{1 - \rho^2(T_i, T^*)} \quad (5)$$

Method 2: Approximate CS using mean M/R and GMPMs with logic-tree weights

$$\mu_{\ln Sa(T_i) | \ln Sa(T^*)} \approx \sum_k p_k^l \mu_{\ln Sa, k(T_i) | \ln Sa(T^*)} \quad (6)$$

$$\sigma_{\ln Sa(T_i)|\ln Sa(T^*)} \approx \sqrt{\sum_k p_k^l \left(\sigma_{\ln Sa, k(T_i)|\ln Sa(T^*)}^2 + \left(\mu_{\ln Sa, k(T_i)|\ln Sa(T^*)} - \mu_{\ln Sa(T_i)|\ln Sa(T^*)} \right)^2 \right)} \quad (7)$$

Method 3: Approximate CS using GMPM-specific mean M/R and GMPMs with deaggregation weights

$$\sigma_{\ln Sa, k(T_i)|\ln Sa(T^*)} \approx \sigma_{\ln Sa, k}(\bar{M}_k, \bar{\theta}_k, T_i) \sqrt{1 - \rho^2(T_i, T^*)} \quad (9)$$

$$\begin{aligned} \mu_{\ln Sa, k(T_i)|\ln Sa(T^*)} &\approx \mu_{\ln Sa, k}(\bar{M}_k, \bar{R}_k, \bar{\theta}_k, T_i) \\ &+ \rho(T_i, T^*) \sigma_{\ln Sa, k}(\bar{M}_k, \bar{\theta}_k, T_i) \bar{\epsilon}_k(T^*) \end{aligned} \quad (8) \quad \mu_{\ln Sa(T_i)|\ln Sa(T^*)} \approx \sum_k p_k^d \mu_{\ln Sa, k(T_i)|\ln Sa(T^*)} \quad (10)$$

$$\sigma_{\ln Sa(T_i)|\ln Sa(T^*)} \approx \sqrt{\sum_k p_k^d \left(\sigma_{\ln Sa, k(T_i)|\ln Sa(T^*)}^2 + \left(\mu_{\ln Sa, k(T_i)|\ln Sa(T^*)} - \mu_{\ln Sa(T_i)|\ln Sa(T^*)} \right)^2 \right)} \quad (11)$$

Method 4: “Exact” CS using multiple causal earthquake M/R and GMPMs with deaggregation weights

$$\sigma_{\ln Sa, j, k(T_i)|\ln Sa(T^*)} = \sigma_{\ln Sa, k}(M_j, \theta_j, T_i) \sqrt{1 - \rho^2(T_i, T^*)} \quad (13)$$

$$\begin{aligned} \mu_{\ln Sa, j, k(T_i)|\ln Sa(T^*)} &= \mu_{\ln Sa, k}(M_j, R_j, \theta_j, T_i) \\ &+ \rho(T_i^*, T_i) \epsilon_j(T^*) \sigma_{\ln Sa, k}(M_j, \theta_j, T_i) \end{aligned} \quad (12) \quad \mu_{\ln Sa(T_i)|\ln Sa(T^*)} = \sum_k \sum_j p_{j, k}^d \mu_{\ln Sa, j, k(T_i)|\ln Sa(T^*)} \quad (14)$$

$$\sigma_{\ln Sa(T_i)|\ln Sa(T^*)} = \sqrt{\sum_k \sum_j p_{j, k}^d \left(\sigma_{\ln Sa, j, k(T_i)|\ln Sa(T^*)}^2 + \left(\mu_{\ln Sa, j, k(T_i)|\ln Sa(T^*)} - \mu_{\ln Sa(T_i)|\ln Sa(T^*)} \right)^2 \right)} \quad (15)$$

Implementations

The refined CS computational methods increase with accuracy and complexity. Several factors contribute to the accuracy of approximations. First, the importance of considering multiple causal earthquakes depends upon how many differing causal earthquake M/R values contribute significantly to the hazard. In addition, variation in other parameters besides M and R , such as

depth to the top of rupture for different source types, can affect the accuracy of the approximation since they contribute to the Sa prediction. Second, the similarity of the GMPMs affects approximations in their treatment. For cases where the ground motion predictions for a given M/R vary significantly between models, approximate treatment of GMPMs is less effective. Third, as the GMPM deaggregation weights differ more from the GMPM logic-tree weights,

approximate treatment of those weights works less effectively. The exact conditional standard deviation is always higher than approximate results (Fig. 3b) because of the additional contribution from the variance in mean logarithmic spectral accelerations (Fig. 3a) due to variation in causal earthquakes and GMPMs. The impact of CS approximations on engineering decisions depends upon the difference between approximate and exact spectra: as the difference increases, more refined target spectra will have increasing benefits for ground motion selection and structural response assessment (Lin et al. 2013a).

The deaggregation of ground motion prediction models and the exact conditional mean spectrum (incorporating multiple causal earthquakes and multiple GMPMs) have been implemented in the United States Geological Survey hazard mapping tools (<http://geohazards.usgs.gov/deaggint/2008/>). Carlton and Abrahamson (2014) proposed an alternative Method 2.5 for a simplified implementation of the CS, which gives similar results to Method 3 in Lin et al. (2013a). Deaggregation weights, instead of logic-tree weights, of GMPMs were recommended when multiple GMPMs were used to compute the CS (e.g., Lin et al. 2013a; Carlton and Abrahamson 2014). Gulercce and Abrahamson (2011) extended the CS concept to vertical ground motions. Bradley (2010) developed a generalized conditional intensity measure approach to include intensity measures other than S_a .

Ground Motion Selection Algorithms

The conditional spectrum can be used as the target spectrum to select “representative” ground motions from a ground motion database for performance-based earthquake engineering. A computationally efficient algorithm (Jayaram et al. 2011) suitable for such CS-based ground motion selection (http://www.stanford.edu/~bakerjw/gm_selection.html) computes a target spectrum, and then selects and scales ground motions from the PEER NGA database to match the target spectrum mean and variance. This

selection algorithm (1) probabilistically generates multiple response spectra from a target distribution, and then (2) selects recorded ground motions whose response spectra individually match the simulated response spectra. (3) A greedy optimization technique further improves the match between the target and the sample means and variances. This algorithm has been adopted by the global earthquake model (<http://www.globalquakemodel.org/>) for ground motion selection. Alternative algorithms that can be used for CS-based ground motion selection include those by, e.g., Wang (2011) and Bradley (2012).

If the uniform hazard spectrum or the conditional mean spectrum, instead of the conditional spectrum, is used as the target spectrum to select (and optionally scale) ground motions, the PEER ground motion database (http://peer.berkeley.edu/products/strong_ground_motion_db.html) is an online tool appropriate for such applications. In addition to CS-based ground motion selection (as shown in Fig. 1a), Jayaram et al. (2011) algorithm can also be modified to accommodate CMS- and UHS-based ground motion selection, as illustrated in Fig. 1b, c respectively.

Hazard Consistency in Risk-Based Assessments

Risk-based assessment estimates the mean annual rate of exceeding a specified structural response amplitude. The conditional spectrum computation requires specification of a conditioning period. The sensitivity of risk-based assessment results to the choice of conditioning period using CS-based ground motion selection is investigated in Lin et al. (2013b). This study focuses on risk-based assessments, with a specific emphasis on the rates of exceeding various levels of peak story drift ratio (i.e., drift hazard calculations) in the structure. Some additional engineering demand parameters (EDPs) are also considered, such as the peak floor acceleration over the full building heights, a single-story story drift ratio, and a single-story floor acceleration. The primary structure considered is a 20-story reinforced concrete frame structure

Conditional Spectra, Fig. 4 Risk-based assessments of (a) peak story drift ratio and (b) peak floor acceleration of a 20-story reinforced concrete frame structure obtained

from ground motions selected to match the CS, the CMS, and the UHS

assumed to be located in Palo Alto, California, using a structural model (Haselton and Deierlein 2007) with strength and stiffness deterioration that is believed to reasonably capture the responses up to the point of collapse due to dynamic instability.

The risk-based assessments are performed several times, using ground motions selected and scaled to match conditional spectra, where the conditioning period used for these calculations is varied from 0.45 to 5.0 s (i.e., the building's third-mode structural period up to approximately twice the first-mode period). For each case, the risk-based assessment results are found to be similar (Fig. 4). The similarity of the results stems from the fact that the careful record selection ensures that the distributions of response spectra at all periods are nominally comparable, so the distribution of resulting structural responses should also be comparable (to the extent that response spectra describe the relationship between the ground motions and structural responses).

From these results, it is observed that if the analysis goal is to perform a risk-based assessment obtaining the mean annual frequency of exceeding an EDP, then one should be able to obtain an accurate result using any conditioning period, provided that the ground motions are selected carefully to ensure proper representation of spectral values and other ground motion

parameters of interest. Here “proper representation” refers to consistency with the site ground motion hazard curves at all relevant periods, and this is achieved by using the CS approach to determine target response spectra for the selected ground motions. The reproducibility of the risk-based assessment results, for varying conditioning periods, then results from the fact that the ground motion intensity measure used to link the ground motion hazard and the structural response is not an inherent physical part of the seismic reliability problem considered; it is only a useful link to decouple the hazard and structural analysis. If this link is maintained carefully then one should obtain a consistent prediction of the risk-based assessment in every case.

Intensity-Based Assessments and Evaluation of Alternative Target Spectra

Intensity-based assessment estimates structural response given ground motions with a specified intensity level. A study on the sensitivity of intensity-based assessment results to the choice of conditioning period when the CS is used as a target for ground motion selection and scaling is conducted by Lin et al. (2013c). This study also investigates the sensitivity of both risk-based and intensity-based assessments to the choice of target spectrum, including evaluation of the uniform

Conditional Spectra, Fig. 5 Intensity-based assessments of peak story drift ratio (median and logarithmic standard deviation in (a) and (b) respectively) of a

20-story reinforced concrete frame structure obtained from ground motions selected to match the CS, the CMS, and the UHS

hazard spectrum and the conditional mean spectrum.

The study shows the different effects of conditioning periods on intensity-based and risk-based assessments. In contrast to risk-based assessments, which are relatively insensitive to the choice of conditioning period in the CS, the choice of conditioning period for the CS can substantially impact structural response estimates for an intensity-based assessment (NIST 2011). It is therefore critical to specify the structural analysis objective clearly.

The study also demonstrates the importance of target spectrum. For intensity-based assessments, use of the CMS, instead of the CS, does not significantly affect the median response estimates (Fig. 5a) but does decrease both the dispersion of the response (Fig. 5b) and the probability of collapse, while use of the UHS typically results in higher median response (Fig. 5a). For risk-based assessments, use of the CMS, instead of the CS, results in underestimation of structural response hazard due to the omission of spectral variability (Fig. 4), while use of the UHS results in overestimation in the structural response hazard (Fig. 4).

An important issue regarding conditioning period arises when an intensity-based assessment is being used and the purpose is to compute the mean or median response associated with an $Sa(T^*)$ having a specified probability of

exceedance (e.g., for a building-code-type check). In this extremely common case, the response prediction will always change depending upon the choice of conditioning period. This comes from the fact that the choice of conditioning period is an inherent part of the problem statement, and so in this case changing the conditioning period changes the question that is being asked. For example, computing the median drift response for a building subjected to a 2 % in 50 year exceedance $Sa(1 \text{ s})$ is not the same as computing the median drift response for a building subjected to a 2 % in 50 year exceedance $Sa(2 \text{ s})$; these are two different questions. Resolution of this issue likely lies in identifying a conditioning period and performance check that, when passed, confirms satisfactory reliability of the structural system.

Summary

The conditional spectrum (CS) is a target response spectrum (with mean and variance) for ground motion selection to perform nonlinear dynamic analysis. The computation of the CS requires (1) input earthquake parameters of magnitude, distance, relevant seismological and site characteristics (e.g., fault type and soil type); (2) specification of a conditioning period; (3) ground motion prediction model(s) (GMPMs)

to estimate mean and standard deviation of logarithmic spectral accelerations; and (4) correlation model(s) to relate spectral accelerations between different periods of vibration. Refined computation of the CS incorporates multiple causal earthquakes and multiple ground motion prediction models. The level of complexity in computation increases from Methods 1 (single earthquake and single ground motion prediction model) to 4 (multiple earthquakes and multiple ground motion prediction models with corresponding deaggregation weights). Factors that affect the accuracy of the approximations include (1) the input causal earthquake parameters, (2) the GMPMs used, and (3) the GMPM deaggregation weights. Hence, exact calculation methods may be needed for locations with hazard contributions from multiple earthquake sources especially with multiple source types, and/or for sites with larger variation in predictions from various GMPMs (Lin et al. 2013a). An intermediate method, Method 2.5, was proposed by Carlton and Abrahamson (2014) as a simpler practical alternative to Method 3 in Lin et al. (2013a). Probabilistic seismic hazard deaggregation of GMPMs (Lin and Baker 2011), which computes the relative contribution of GMPMs to a given intensity level, facilitates the refined CS computation. Deaggregation weights, instead of logic-tree weights, of GMPMs were recommended when multiple GMPMs were used to compute the CS (e.g., Lin et al. 2013a; Carlton and Abrahamson 2014). Notable extensions of the CS concept include the CS for vertical motions (Gulerce and Abrahamson 2011) and the generalized conditional intensity measure (Bradley 2010).

The computation and use of the CS advances hazard-consistent ground motion selection for performance-based earthquake engineering. The automation via USGS hazard mapping interface and ground motion selection web-based algorithms enhances practical applications of the CS. Challenges in the CS remain in (1) the choice of the conditioning period, (2) the appropriate question to ask in design-orientated intensity-based assessment, (3) a larger number of distinct ground motions that are used at various intensity levels, and (4) issues related to scaling ground

motions. Progress has been made towards the effect of conditioning period in intensity- and risk-based assessments (Lin et al. 2013b, c; Carlton and Abrahamson 2014), the performance goal and design check via design spectrum calibration (Loth and Baker 2013), and a new method termed “adaptive incremental dynamic analysis” (AIDA) (Lin and Baker 2013) that allows overlap of ground motions across intensity levels. Research is ongoing to provide insights on the current engineering practice of ground motion scaling and the seismological counterpart in direct ground motion simulation.

Part of this entry has been taken from: Marin, C., Bovolo, F., Bruzzone, L.: *Building Change Detection in Multitemporal Very High Resolution SAR Images*, has been accepted for publication to IEEE Transaction on Geoscience and Remote Sensing.

It is worth noting that the incidence angle can be different from the incidence angle of SM images.

Equations 4 and 5 hold assuming flat-roof buildings with rectangular layout and SAR images in slant-range geometry.

Vice-versa a new buildings (ω_{c2}) is identified if the order of appearance of the pair increased/decreased is inverted with respect to the range direction as described in section “Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images”

Introduction

Earthquakes have struck cities around the globe causing injury, loss of life, and damage to human settlement since the ancient times. In the last years large earthquakes have been reported globally affecting wide geographical areas and a relevant number of people. A remarkable example was the 2011 Tohoku earthquake with moment magnitude scale (MMS) of 9.0. The earthquake caused 15,884 deaths, 6,147 injured, and 2,636 people missing across twenty prefectures, as well as 129,316 buildings totally collapsed, 263,845 buildings half collapsed, and 725,760 buildings partially damaged (World Bank 2012). The earthquake triggered tsunami waves that caused the nuclear accidents at three reactors in the Fukushima Daiichi Nuclear Power Plant complex and the associated evacuation zones affecting hundreds of thousands of residents (World Bank 2012). Moreover, the earthquake and tsunami also caused extensive and severe structural damage in northeastern Japan, including heavy damage to roads and railways, as well as fires in many areas, and a dam collapse. The World Bank has estimated an economic damage of USD 210 billion, making it the costliest natural disaster in the world history (World Bank 2012). Another relevant example is the 2009 L’Aquila earthquake (Italy) with 6.3 MMS. The earthquake caused damages to a relevant number of medieval buildings in the city of L’Aquila: several buildings collapsed, about 300 people died, and about

1,500 people were injured making this event the deadliest earthquake to hit Italy since 1980. The list of earthquakes and their damages that occurred globally can be continued. Indeed, according to the United States Geological Survey (available online: <http://earthquake.usgs.gov/>) records, the frequency of such catastrophic events is high: 332 earthquakes with an MMS of 7 or higher have been reported in the last 20 years.

In order to understand and possibly mitigate the impact of such events on the citizenry, several governmental initiatives and research activities have been carried out in the past (e.g., the international charter on space and major disasters (available online: <http://www.disasterscharter.org/>), UN-OSAT (available online: <http://www.unitar.org/unosat/>), or the geohazard supersites and natural laboratories (available online: <http://supersites.earthobservations.org/>) to tackle each of the phases of such events. In detail a catastrophic event can be partitioned in three characteristic phases: (1) before the event in which a system of risk assessment for early warning is essential, (2) the moment the event occurs in which a disaster-alerting system is the main priority, and (3) after the event in which an emergency response with impact assessment has to be initiated.

Focusing on the third phase, among all the possible damages caused by natural disasters, the building damages contribute mostly to the casualties (Dell'Acqua and Gamba 2012). Nonetheless, the identification of struck built-up areas may be particularly complex because of both the possible large extension of the affected region and the difficulties to access remote villages. In this scenario Earth observation (EO) data acquired by remote-sensing satellites represent a useful tool to support decisions of civil protection authorities after the event. Indeed, satellites equipped with optical or synthetic aperture radar (SAR) sensors can monitor large regions in a quick, synoptic, and uncensored manner. In particular, SAR systems present the advantage over optical sensors to be independent from sun illumination and to be relatively insensitive to atmospheric weather conditions. This ensures the data

availability during the crisis event even though the site affected by the crisis event is covered by clouds or if the satellite is passing during night.

Since 2008 a new generation of SAR missions (i.e., TerraSAR-X, TanDEM-X, and COSMO-SkyMed) has regularly acquired data over Earth. These systems can perform acquisitions using two high-resolution modes called StripMap (SM) and SpotLight (SL). SM is characterized by a wide coverage (around 1,500 Km²) with a high resolution (3–5 m), whereas SL is characterized by a moderate coverage (around 100 Km²) with a very high resolution (1 m). This means that the two SAR modes are complementary to each other and can be used for performing different duties during the emergency response phase. SM mode can be used for identifying the blocks of the city more hit by the earthquake, whereas the SL images can be used to identify detailed information about collapsed buildings. It is worth noting that, these SAR missions are daily populating a huge archive of multitemporal images. This archive can be employed to detect changes in the state of an object or phenomenon by jointly observing the data acquired at different times over the same geographical area. This process, which is known in the literature as change detection, has got an increase of interest from the scientific community in the last decade, and a relevant number of novel techniques were developed to achieve this goal. Nonetheless, SAR images with a resolution ranging from 5 m (referred in this work as high-resolution images) of the SM images up to 1 m (referred in this work as very high-resolution images) of the SL images are more heterogeneous than old-generation sensor images, which have resolution generally ranging from 10 to 30 m (Soergel et al. 2006; Brenner and Roessing 2008). In high-resolution (HR) and very high-resolution (VHR) images, objects that are considered homogeneous from a semantic point of view (e.g., buildings) show a signature that is inhomogeneous at high spatial resolution because of the scattering contributions from sub-objects (e.g., facade and roof of a building). Furthermore, on the one hand the side-looking illumination

required by SAR systems leads to phenomena such as layover, shadow, and multipath signals (Dong et al. 1997; Franceschetti et al. 2002), which are very marked in urban areas. On the other hand, the appearance of a ground object depends on radar system parameters (i.e., wavelength, polarization, pulse length, incidence angle, look direction, etc.), surface feature properties (e.g., dielectric constant), and environmental variables (e.g., groundwater content) (Xia and Henderson 1997). On top of these aspects, SAR images are corrupted by speckle noise.

All these factors, within the context of the multitemporal analysis, make the problem of the detection of changes complex. Due to the high resolution, a large set of possible changes with different semantic meanings and scales are detectable in multitemporal HR and VHR SAR images. In general, each change may be associated with the cause of the change itself (Bruzzone and Bovolo 2013) and may present an extension that varies from the single pixel to a relevant portion of the entire scene. For instance, it is possible to distinguish among changes due to the anthropogenic activity, the phenological evolution of the vegetation, and the natural disaster effects. Depending on the application, some of these may be of interest to the end users, whereas others may not (Bovolo et al. 2013). In addition, external factors, such as different content of water on the ground due to different weather conditions, may affect the local back-scattering behaviors at the two considered dates also in absence of any change. Therefore, the same object may show different values of back-scattering even though it is not affected by a relevant change. This invalidates the assumption that two SAR images acquired on the same geographical area at different times are similar to each other except for the presence of changes occurred on the ground, which is often considered for medium-resolution SAR images. Thus, the use of standard pixel-based change detection techniques (Bazi et al. 2005) is not possible as they would be affected by a large amount of false alarms. Given the complexity of the problem, also standard context-based techniques based on a local neighborhood

analysis (Inglada and Mercier 2007) would fail to solve the problem since they are not able to properly take into account the high geometrical detail of HR and VHR data. To achieve change detection in HR and VHR SAR images, the analysis between the multitemporal images should be performed at a higher conceptual level that models the source of change from the prospective of interactions with the incidence electromagnetic wave.

Numerous studies have been recently presented in the literature that deal with the problem of recognition of changes in urban areas using VHR SAR images (Matsuoka and Yamazaki 2004; Chini et al. 2009; Ehrlich et al. 2009; Brunner et al. 2010; Balz and Liao 2010; Dekker 2011; Dell'Acqua et al. 2011; Dong et al. 2011; Jin et al. 2011; Dong and Shan 2013; Poulain et al. 2011; Tao et al. 2012; Brett and Guida 2013). In detail, Matsuoka and Yamazaki (2004), Chini et al. (2009), Ehrlich et al. (2009), Brunner et al. (2010), Balz and Liao (2010), Dekker (2011), Dell'Acqua et al. (2011), Dong et al. (2011), Jin et al. (2011), and Dong and Shan (2013) are focused on the detection of earthquake damages, Poulain et al. (2011) are focused on the building databases' updating, and Tao et al. (2012) address the detection of changes due to the urban evolution. The strategies that are exploited in these works include post-event supervised analysis (Ehrlich et al. 2009; Balz and Liao 2010; Dong et al. 2011; Jin et al. 2011; Dong and Shan 2013), joint use of optical and SAR data (Chini et al. 2009; Brunner et al. 2010), joint use of LiDAR and SAR data (Tao et al. 2012), unsupervised detection of damages at the level of aggregated blocks (Matsuoka and Yamazaki 2004; Dekker 2011), or GIS polygons (Dell'Acqua et al. 2011). Despite the great interest, the only work that addresses the problem of building change detection using multitemporal VHR SAR data in an unsupervised way is presented in (Brett and Guida 2013). In detail, the authors present an approach to the detection of damaged structures in urban areas from VHR SAR images, which is based on the multitemporal detection of the double-bounce

line generated by the multiple backscattering between the wall of the building and the ground. If a double-bounce line appears (disappears) between two acquisitions, a new (destroyed) building is recognized. Double bounce is one of the salient primitives characterizing a building in SAR images. It is known from the literature that at least other two primitives characterize the building footprint: the layover and the shadow. Therefore, the partial modeling of the source of change used in (Brett and Guida 2013) may generate a relevant number of missed alarms. Furthermore, the double-bounce line of a building alone is not a reliable feature for the identification of buildings because in several cases it may be not visible (Ferro et al. 2011).

In this work we present an approach that exploits the characteristics of the two complementary acquisition modes (i.e., StripMap and SpotLight) to: (i) quickly and automatically identify the areas severely affected by a catastrophic event (i.e., hot spots), such as an earthquake, by analyzing images characterized by a large coverage and a medium to high geometrical resolution and (ii) analyze images characterized by very high geometrical resolution acquired over hot spots in order to detect collapsed buildings. The effectiveness of the proposed approach is demonstrated in experimental results obtained on COSMO-SkyMed multitemporal images acquired in 2009 on the city of L'Aquila (Italy) before and after the earthquake that hit the region.

This entry is organized into five sections. Section “[Backscatter of Buildings in Synthetic Aperture Radar](#)” presents and reviews the fundamentals of the backscattering mechanism of buildings in monotemporal images. Moreover, it proposes an analysis of this mechanism for bitemporal SAR images, which is based on the concepts expressed for the monotemporal case. The proposed approach to building change detection is described in section “[Proposed Approach to Damage Detection](#).” Section “[Dataset Description and Experimental Results](#)” presents the dataset and shows the experimental results. Section “[Summary](#)” draws the conclusions of the work.

Backscatter of Buildings in Synthetic Aperture Radar

SAR is an active radar system operating in the microwave region of the electromagnetic spectrum generally between P band (i.e., 0.1–0.39 GHz) and Ka band (i.e., 26–40 GHz). The inherent characteristics of SAR measurements render this sensor sensitive to dielectric and roughness properties of the investigated natural media. The active operating mode makes this kind of sensor independent of solar illumination allowing day and night acquisitions. Moreover, the effect of clouds, fog, rain, smokes, etc., is mostly avoided due to the operation of the sensor in the microwave portion of the electromagnetic spectrum. SAR systems illuminate the scene using a side-looking geometry (see Fig. 1). The antenna of the radar system is mounted on a flying platform. Its horizontal and vertical axes are parallel and orthogonal to the azimuth direction, respectively. The angle between nadir and the radar beam direction is called incidence angle and it is usually denoted by θ . Such a system illuminates the Earth surface with microwave pulses and receives the electromagnetic signal backscattered from the illuminated scene. By means of signal processing techniques that exploit the Doppler shifts of the received electromagnetic echoes, SAR systems are able to synthesize a two-dimensional high-spatial resolution image from all the received signals.

The side-looking geometry of SAR together with non-flat terrain causes geometric distortions, such as foreshortening, layover, and shadow effects, which are visible as relatively bright and dark regions in SAR imagery, respectively. Furthermore, SAR data are affected by a characteristic noise called speckle, which causes the granular appearance of SAR imagery. This is the result of constructive and destructive interferences between the complex returns from the scatterers in a resolution cell.

Several sensor operation modes for acquiring SAR data were developed in the past. The most common modes which are implemented in spaceborne SAR missions are StripMap (SM) and SpotLight (SL). In the SM (see Fig. 2a) the

Damage Detection in Built-Up Areas Using SAR Images, Fig. 1 Side-looking geometry of SAR systems (Courtesy of Dominik Brunner)

Damage Detection in Built-Up Areas Using SAR Images, Fig. 2 SAR operation modes. (a) StripMap mode. (b) SpotLight mode (Courtesy of Dominik Brunner)

radar antenna points along a fixed direction with respect to the flight path. As the platform moves, the resulting image covers a strip of the ground surface. The extension of the imaged area in azimuth direction is limited only by the power and free memory available onboard of the satellite, whereas the resolution in range direction is constrained by half of the actual antenna length. Generally speaking for the new SAR generation, the standard coverage is of about 1,500 Km² with

a resolution that varies between 1.5 and 5 m in ground range and about 3 m in azimuth depending on the platform and acquisition parameters. In the SL mode (see Fig. 2b) the azimuth resolution is improved by increasing the length of the synthetic antenna. This is done by steering the antenna beam so that to illuminate the same area on the ground during the acquisition. Nonetheless, the improvement in the azimuth resolution is at the expense of the spatial

coverage. The standard coverage is in fact of about 100 Km^2 (instead of $1,500 \text{ Km}^2$) with a resolution that varies between 1 and 3.5 m (instead of 1.5 to 5 m) in ground range and 1 m (instead of 3 m) in azimuth depending on the platform.

In the rest of the section, we analyze the backscattering mechanism with respect to the variation of the acquisition geometry when isolated buildings with rectangular layout are sensed by HR or VHR SAR (section “[Building Backscattering Mechanism in Single-Detected HR and VHR SAR Images](#)”). This analysis is used to interpret multitemporal HR and VHR SAR images in order to study and model the effects associated with new/demolished building (section “[Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images](#)”). This study gives the base for the development of the proposed approach.

Building Backscattering Mechanism in Single-Detected HR and VHR SAR Images

In the literature several works have been presented that analyzed the scattering mechanism for different building models in order to derive their appearance in SAR images (Bennett and Blacknell 2003; Thiele et al. 2007; Brunner et al. 2010). These analyses make use of the geometrical optics (ray theory) approximation in order to model the electromagnetic scattering. This has the power to be intuitive and geometrically accurate even though the electromagnetic interactions and the transmission configurations of the antenna are not taken into account. In geometrical optics the wave propagation is described by rays, which are modeled as lines perpendicular to the wavefronts, that may be reflected, absorbed, or split at the interface between two different media. By knowing the geometry of acquisition of the SAR system and by exploiting trigonometric functions, it is possible to simulate the appearance of a building in HR and VHR SAR images.

Let us consider an isolated flat-roof building with dimensions $w_1 \times w_2 \times h$ illuminated by a SAR sensor that is moving along the azimuth direction and is illuminating the building from the left (Fig. 3a). Let us consider a building

model that does not take into account the building features such as windows, eaves, ridges, railings, and so on. This is equivalent to analyze the image at the scale level comparable with the building, and it allows us to derive the appearance of a building without losing generality. The acquisition geometry of a SAR system (Fig. 3a) is characterized by two parameters: the incidence angle θ (i.e., the angle defined by the incident radar beam and the normal to the intercepting surface) that is generally included between 20° and 55° and the aspect angle $0^\circ \leq \theta < 90^\circ$ (i.e., the angle between the azimuth direction and the orientation of an object in the horizontal plane). For the sake of argument, let us first assume that the SAR sensor illuminates the section A-A (light-blue area in Fig. 3a) of the building from a fixed position in the azimuth. Figure 3b shows in a qualitative way the amplitude of the backscattering projected in ground range and slant range of A-A. Following (Brunner et al. 2010) the main contributions that can be identified are the return a from the ground, the double-bounce effect b caused by the dihedral reflector formed by the building wall and the ground, the backscattering c from the front wall, the returns d from the building roof, and the shadow area e (see Fig. 3b). As one can observe the contributions from the ground, the wall and the roof are summed up into an area in front of the building ($a + c + d$), which appears brighter than each of these contributions taken singularly because of their superposition. This phenomenon, called layover, occurs when SAR sensors are imaging a surface with a slope steeper than the incidence angle θ , such as the wall of a building. It is worth noting that the length of the layover, the roof contribution, and the shadow depends on the width (w) and the height (h) of the section A-A and the incidence angle θ .

In order to derive the appearance of the whole building in a VHR SAR image, it is necessary to perform the aforementioned analysis for all the sections parallel to A-A that form the building. Nevertheless, as the width of each parallel section changes, the length of each mentioned contribution changes accordingly. Three cases can be observed on the basis of the relationship between

Damage Detection in Built-Up Areas Using SAR Images, Fig. 3 Example of backscattering mechanism for a flat-roof building. (a) Simplified model of a flat-roof building oriented with a given aspect angle θ . The SAR sensor is moving on the left of the building. Theoretical scattering model for a given incidence angle θ in the case the sensor is illuminating. (b) Only the section A-A of the building from a fixed position in the azimuth (the

backscattering is reported in both slant and ground range). (c) The whole extension of the building (the backscattering is in slant-range geometry). Different gray levels represent different amplitudes. Example of (d) a real flat-roof building in Trento (Italy) acquired at 1 m resolution by TerraSAR-X in slant range (SAR illumination is from the left courtesy of DLR). (e) The same building in an optical image (GeoEye – Google)

the width w of the section A-A and the limit value w_b defined as (Bennett and Blacknell 2003; Soergel et al. 2003):

$$w_b = \frac{h}{\tan \theta} \quad (1)$$

where h and θ are the height and the incidence angle of the building, respectively. Figure 3a

shows the case in which $w > w_b$. As the width of the section w decreases, the layover and shadow result larger, whereas the backscattering from the roof will be absorbed in the layover. This behavior is valid up to the limit condition $w = w_b$ for which the whole roof contribution is sensed in the layover area before the double bounce. In the case $w < w_b$ two contributions to layover areas can be distinguished: one due to the

ground, the front wall, and the roof ($a + c + d$) and one due to the backscattering from the ground and the front wall of the building ($a + c$). Figure 3c shows the building radar footprint generated from the building of Fig. 3a. It is a convex polygon made up of (i) a bright L-shaped region due to the layover, (ii) a dark L-shaped region due to the shadow, (iii) a bright L-shaped line due to the double bounce, (iv) a rectangular region due to the direct return from the roof, and (v) two bright triangular regions due to the layover of only ground and wall ($a + c$). It is worth noting that since in the acquisition phase the radar is moving, the shadow casted by a ground object is moving as well resulting in a blurring of the border of the shadow (Zhang et al. 2013; Groen et al. 2009) (see the dotted area in Fig. 3c). By comparing Fig. 3c, d, it is possible to observe that the geometrical optics approximation can effectively describe the real behavior of scattering in VHR SAR images.

The same building may appear differently in SAR images according to the value of the aspect angle ϕ . When ϕ is approaching the limit values $\phi = 0^\circ$ and $\phi = 90^\circ$, the layover, the double bounce, and the shadow change by approaching a rectangular shape. A special attention has to be given to the double-bounce line with respect to the variation of ϕ (Franceschetti et al. 2002; Dong et al. 1997). In Ferro et al. (2011) an empirical study on the relationship between the strength of the double bounce and the aspect angle highlighted that the double-bounce contribution drops off significantly if the aspect angle increases from $\phi = 0^\circ$ up to 10° , whereas it decays moderately for higher angles. θ also affects the appearance of a building in VHR SAR images. By reverting Eq. 1, it is possible to derive a limit value θ_b that is equivalent to w_b . Nonetheless, in urban areas the choice of θ can be critical for two reasons: (i) the value of backscattering is related to θ , i.e., small value of θ generates higher value of backscattering and vice versa; and (ii) a large value of θ generates long shadow areas and small layover areas and vice versa. Thus, the backscatter has a dependence on the incidence angle, and there is potential for choosing optimum configurations for different applications.

The same analysis described in this section for flat-roof building can be conducted for other building models, e.g., gable-roof buildings (Brunner et al. 2010). The outcomes of such a study can be summarized as follows: the footprint of any type of isolated buildings with a rectangular base is given by a specific convex pattern made up of a bright area (due to layover and double-bounce effects) followed by a dark area (due to the shadow effect). These features may have different thickness, shape, and internal variability of backscattering on the basis of the considered building structure and material. Nevertheless, they will systematically arise when SAR systems are sensing an isolated building with an adequate resolution.

Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images

The aim of this section is to analyze the behavior of the radar backscattering in multitemporal images when a building changes by taking into account the single data analysis carried out in the previous section. This analysis introduces the basic concept on which the proposed approach is based. In order to properly illustrate the problem, let us focus on a building that fully disappears between two acquisitions. Let us assume to sample this situation acquiring one image when (i) the building is standing and (ii) the building is totally dismissed. Let us assume to use a VHR SAR system configured with the same geometrical parameters (i.e., same incidence angle θ and same azimuth path) for the two acquisitions. As in section “Building Backscattering Mechanism in Single Detected HR and VHR SAR Images,” let us start the analysis by comparing the backscattering considering the illumination source fixed at a given point along the azimuth direction corresponding to section A-A (Fig. 1a) in the case the building is present. The backscattering profile obtained for the standing building is reported in Fig. 4a. As one can notice, the backscattering behavior is the same as the one obtained in the previous section and reported in Fig. 3b. Whereas for the case of totally dismissed building, by assuming bare ground as depicted in Fig. 4b, the value of backscattering is approximately

Damage Detection in Built-Up Areas Using SAR Images, Fig. 4 Building scattering mechanisms for a fixed illumination source corresponding to: (a) a section of a building and (b) bare ground. The comparison of Figures (a) and (b) describes the multitemporal scattering

mechanism in the cases (a) a new building is built up (the envelope of backscattering of bare soil is reported for comparison in *dotted line*) and (b) a building is dismissed (the envelope of backscattering of the building in (a) is reported in *dotted line*)

constant. By comparing Fig. 4a, b, one can observe that the region with a high value of backscattering due to the layover $a + c + d$, the double bounce b , and the roof contribution d decreases its value when the building disappears, whereas the region hidden by the shadow e becomes visible to the line of sight of the radar and therefore increases its value (the dashed line in Fig. 4a represents the envelope of backscattering of bare ground). In other words, in the case of a new building we are likely to observe a structured pattern made up of two regions having increase and decrease of the backscattering oriented from near-to-far range. Vice versa if we consider the case in which a building disappears between two acquisitions, we expect that a structured pattern made up of two regions having decrease and increase in the backscattering values arises in near-to-far range (the dashed line in Fig. 4b represents the envelope of the backscattering amplitude of a building).

This specific multitemporal behavior obtained when the illumination source is fixed at a given position in azimuth can be used to retrieve the appearance of new/demolished buildings in multitemporal VHR SAR images by repeating the same analysis for all the sections parallel to A-A that form the scene. The obtained new/destroyed building radar footprint is made up of a pattern included in a convex polygon.

The pattern includes two regions that can be classified as: (i) area of increase of the value of backscattering and (ii) area of decrease in the value of backscattering. The order of appearance of these two regions along the near-to-far-range direction defines if the pattern is due to new buildings (see Fig. 5a), i.e., the increase area (in this work depicted conventionally in magenta) is closer to the sensor than the area of decrease (in this work depicted conventionally in green) or demolished building (see Fig. 5b), i.e., the decrease area is closer to the sensor than the increase area.

By taking into account the analysis done in section “Building Backscattering Mechanism in Single Detected HR and VHR SAR Images” on the radar signature of a general isolated building, it is possible to derive the appearance of the radar footprint of any type of newly built-up or destroyed buildings in VHR SAR multitemporal images. In detail, the change building radar footprint can be identified checking: (i) the presence of both the regions of increase and decrease in backscattering, (ii) the proportion between the areas (in pixels) of the regions of increase and decrease in backscattering (the proportion depends on the incidence angle of the acquisition), (iii) the equality between the lengths of the regions of increase and decrease in backscattering in the azimuth direction, and (iv) the alignment of the regions of increase and decrease in

Damage Detection in Built-Up Areas Using SAR Images, Fig. 5 Building scattering mechanisms in multitemporal VHR SAR images (illumination source on the *left*). Idealized map highlighting decrease and increase

in the value of backscattering (unchanged pixels are in white) obtained in the case of (a) new and (b) fully demolished building

backscattering with respect to the range direction, i.e., the barycenters of the two regions lay on the line with the range (as the regions in the model are not regularized, the barycenters were calculated by means of the geometric decomposition method). The order of appearance of the two regions of increase and decrease in backscattering value determines if the changed building radar footprint is due to a new or a destroyed building.

It is worth noting that the regions of change may have different thickness, shape, and variability of backscattering change on the basis of the considered building structure and acquisition geometry. Despite this variability, the pattern will systematically arise when SAR systems are sensing an isolated building with an adequate resolution (Bovolo et al. 2012). Hence, a method for the detection of the changed building based on this concept results to be robust to both the noise and the uncertainty (i.e., the impossibility of modeling the reality precisely) of multitemporal VHR SAR data.

Proposed Approach to Damage Detection

Let us assume to analyze two HR amplitude SAR images I_1 and I_2 acquired in StripMap mode before (pre-event) and after the event

(post-event), respectively, which have the same incidence angle and centered over the epicenter of the event. The goal is to detect the areas severely damaged by the event (i.e., hot spots) in order to quickly organize the rescue operations. The most critical issue for the identification of the damages is related to the presence of many possible kinds of changes on the ground. A single site may include many kinds of change that show significantly different characteristics in terms of size, shape, and semantic meaning. Note that not all the changes are associated to the built-up site, and thus, they are not relevant for the rescue operation. The analysis of SM image allows the detection of large portions of changed areas. Here we refer them as hot spots. The obtained hot spots are then exploited to drive the selection of a pre-crisis VHR SAR $X_1^1, \dots, X_1^Q$ and the acquisition of post-crisis VHR SAR images $X_2^1, \dots, X_2^Q$ taken with the same incidence angle. Note that the acquisition of the post-crisis images $X_2^1, \dots, X_2^Q$ should be scheduled on the basis of the detected hot spots. These images are used to perform change detection at high spatial resolution with the goal to detect collapsed buildings with a high level of detail.

Hence, the proposed approach is made up of two main phases: (i) a coarse detection of the areas of change (hot spots) and (ii) a fine detection of the fully collapsed buildings inside each hot spot. Figures 6 and 7 show the block schemes

From $\mathbf{I}_{LR}^{\text{fil}}$ it is possible to isolate the areas affected by a significant backscattering change and that present an extension equal or larger than the resolution of the selected wavelet level $N + 1$. Therefore, in order to detect the hot spots, the selected level has to be comparable to the scale of aggregated buildings' or city blocks' size. As the analysis of SAR images acquired in SM mode involves the processing of large multitemporal images, it is possible that the population of changed pixels is in sharp minority when considering $\mathbf{I}_{LR}^{\text{fil}}$. This may affect the accuracy of the adopted automatic threshold selection technique. In order to address this issue, we use the thresholding method presented in (Bovolo and Bruzzone 2007). This method divides the considered image into sub-images of a given size (splits) and performs the threshold selection considering only the splits that present the highest probability of containing changed splits. This selection allows the definition of a subset of splits in which the class of change shows a higher prior probability than in the whole image. For our purpose, $\mathbf{I}_{LR}$ is split into a set of S sub-images of a user-defined size. The choice of the split size $S_R^{\text{SM}} \times S_A^{\text{SM}}$ is driven by the average extension of the expected changes. Once the size S_R^{SM} and S_A^{SM} are defined, the splits are identified and selected according to their probability to contain a significant amount of changed pixels. The selection is done according to the value of the variance σ_s^2 , $s = 1, \dots, S$, computed on each split. This is a reasonable index for predicting the presence of changes in the log-ratio image since the residual multiplicative noise of the ratio image becomes additive due to the log operator. The desired set $\mathcal{P}_s$ of splits with the highest probability to contain changes is defined by selecting the splits that satisfy the following inequality:

$$\sigma_s^2 \geq \bar{\sigma}^2 + B\sigma_{\sigma^2}, \quad s = 1, \dots, S \quad (3)$$

where $\bar{\sigma}^2$ denotes the average variance of splits, σ_{σ^2} is the standard deviation of the variance of splits, and $B > 0$ is a constant. High values of B result in the selection of only those splits with high variance (i.e., the ones with the highest probability to contain changes); vice versa, low

values of B results in the selection of more splits. The split-based selection allows defining a subset of pixels $\mathbf{I}_s = \{\mathbf{I}_{LR} | \mathbf{I}_{LR} \in \mathcal{P}_s\}$ in which the classes of change show a higher prior probability than in the whole image. Consequently, the statistical estimation of the parameters related to the three probability density functions associated with no change, increase, and decrease of backscattering between the two dates (i.e., ξ_u , ξ^+ , ξ^-) can be correctly derived and used to separate the three classes. Here the thresholding method described in (Bazi et al. 2007) is adopted and the Bayes decision rule for minimum error is applied to separate the three classes. To this end a statistical model for class distributions is required together with an approach for class statistical parameter estimation. The Gaussian model and the well-known expectation-maximization (EM) algorithm (Dempster et al. 1977) are employed to derive $\mathbf{M}_{\text{SM}}$.

It is worth noting that $\mathbf{M}_{\text{SM}}$ does not report any information about the source of the changes. Indeed the changes may be associated to the crisis event as well to other source of change such as phenological changes. By exploiting prior information (e.g., cadastral map) and focusing on changes related to built-up areas, the hot spots possibly related to the crisis event that are in urban areas can be isolated. Nevertheless, among these changes some may be more critical than others. The severity of the change can be inferred considering the prior information available to civil protection or exploiting the intensity and texture information of the SAR images as proposed in (Dell'Acqua and Gamba 2012; Dekker 2011). Once the most relevant hot spots are detected, an algorithm for solving the "packing problem" of acquiring the minimum number of SL acquisitions $\mathbf{X}_2^1, \dots, \mathbf{X}_2^Q$ by covering the highest number of critical hot spots can be applied. Under the assumption the pre-event $\mathbf{X}_1^1, \dots, \mathbf{X}_1^Q$ images have been already acquired, when a crisis occurs the acquisition of $\mathbf{X}_1^1, \dots, \mathbf{X}_1^Q$ can be effectively planned (if not already done) by the outcome of this phase.

Detection of Fully Collapsed Buildings

The aim of the second phase is to detect collapsed buildings considering higher resolution data

acquired in SpotLight mode over the hot spots detected in the previous phase. This is the most challenging part of this work and it requires advanced techniques for change detection. For the sake of notation, and without any loss of validity in the following, we assume that $\varrho = 1$ and thus that critical hot spots can be fully covered by means of a single couple of images $\mathbf{X}_1$ and $\mathbf{X}_2$ acquired with the same incidence angle on the same geographical area at different times t_1 and t_2 , respectively. Let $\Omega = \{\omega_u, \Omega_c\}$ be the set of classes of changes to be identified: ω_u represents the class of unchanged pixels, whereas $\Omega_c = \{\omega_{c1}, \omega_{c2}, \dots, \omega_{cK}\}$ is a meta-class that gathers all the K possible classes (kinds) of change that may arise on the ground. One of the most critical issues dealing with this kind of scenario is related to the presence of many kinds of change on the ground. Nevertheless, in this work we are interested to investigate an urban area with the goal to detect collapsed buildings which usually represent the most critical kind of change in an earthquake emergency. In detail, we consider $K = 4$ classes of change: (i) fully destroyed buildings (ω_{c1}), (ii) new buildings (ω_{c2}), (iii) changes that have a size comparable to a building but do not present the typical pattern of full new/demolished buildings (ω_{c3}), and (iv) all the other changes that do not show a size comparable to a building and are therefore not related to changed buildings (ω_{c4}). In order to achieve this classification, we introduce an approach made up of two stages: (i) identification of the areas affected by changes in the backscattering at the scale of buildings and (ii) exploitation of the backscattering models presented in section “Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images” in order to detect the classes $\Omega_c = \{\omega_{c1}, \omega_{c2}, \dots, \omega_{c4}\}$. Each stage of the proposed method for SL images analysis is explained in detail in the following. The block scheme is reported in Fig. 7.

As described in section “Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images,” under the hypothesis of using a SAR sensor with a resolution comparable to the building size, the signature of isolated new/demolished buildings in multitemporal data

is given by a pattern made up of increase and decrease of backscattering regions. The first stage of the proposed approach is thus devoted to extract the areas that present both a significant increase or decrease in the backscattering value in SL (i.e., ξ_u, ξ^+, ξ^-). Nonetheless, at a resolution of a meter or less, the small objects that form the buildings such as windowsills or rain drains are visible. This results in an inhomogeneous signature of the building, which may affect also the appearance of new/destroyed buildings in multitemporal images rendering the regions of increase and decrease far from being homogeneous. It is worth noting that working at the full resolution of SM images (i.e., between 3 and 5 m) is also problematic due to the massive presence of noise. Therefore, we propose to work at an optimum scale level for representing buildings and not subparts of them, derived from the VHR images. This can be used to identify the regions of increase and decrease of backscattering, which characterize the buildings, with the advantages of (i) reducing the impact on the detection of small changes and thus reducing the false alarm rate and (ii) making it possible a mitigation of the speckle effect on the detection.

In order to work at the scale of a building, we propose to build a multiscale representation of the multitemporal information made up of N scale level. The $(N - 1)$ th resolution level, which represents the optimum scale level, is selected according to the minimum size of the building in the investigated scene. The multiscale representation can be obtained by applying several methods, e.g., Laplacian/Gaussian pyramid decomposition (Burt and Adelson 1983) or wavelet transform (Mallat 1989). Here the two-dimensional discrete stationary wavelet transform (2D-SWT) is exploited, which has the advantage of avoiding the down-sampling after each convolution step (Nason and Silverman 1995). In detail, we used the wavelet-based decomposition and reconstruction of the log-ratio image approach presented in (Bovolenta and Bruzzone 2005) for change detection in medium-resolution SAR images. The log-ratio image $\mathbf{X}_{LR}$, which is derived as $\mathbf{X}_{LR} = \log \mathbf{X}_2 / \mathbf{X}_1$, efficiently points out the differences in

backscattering values. From $\mathbf{X}_{LR}$ a set of multilevel images $\mathcal{X}_{MS} = \{\mathbf{X}_{LR}^0, \dots, \mathbf{X}_{LR}^n, \dots, \mathbf{X}_{LR}^{N-1}\}$ are computed, where the superscript n , $n = 0, \dots, N - 1$ indicates the resolution level. This is done in two steps: a decomposition phase in which $\mathbf{X}_{LR}$ is filtered through a cascade of N filters and a reconstruction phase in which only the information of interest is used to reconstruct the original image at the n th resolution level. According to (Bovolo and Bruzzone 2005), the decomposition is based on 2D-SWT, which applies to the considered image-appropriate level-dependent high- and low-pass filters at each resolution level n . Filter impulse response depends on the selected wavelet family. For each approximation sub-band $\mathbf{X}_{LR}^{LL_{n+1}}$, the inverse stationary wavelet transform (2D-ISWT) is applied $n + 1$ times in order to reconstruct in the image space the set $\mathcal{X}_{MS} = \{\mathbf{X}_{LR}^0, \dots, \mathbf{X}_{LR}^n, \dots, \mathbf{X}_{LR}^{N-1}\}$. For n ranging from 0 to $N - 1$, the images are characterized by resolution that is degraded

approximately by a factor of 2^n . Therefore, as expected by decreasing the resolution, small changes tend to disappear and only changes of a given size are fully preserved. More details on this strategy are given in (Bovolo and Bruzzone 2005).

Once the optimum scale level (opt) has been selected, a change detection (CD) map $\mathbf{M}_{SL}^{opt}$ is derived from $\mathbf{X}_{LR}^{opt}$ according to the split-based thresholding procedure described in the previous section. Since we are considering changes related to buildings, we can determine S_R^{SL} and S_A^{SL} (i.e., the size of split for building analysis at the SL resolution) taking into account the average size of the radar footprint of the changed buildings in the considered radar image. This information can be inferred by considering the actual average size of the buildings, i.e., w_1 , w_2 , and h (see Fig. 3a) in the considered area, and converting it into SAR geometry by applying the following equations (Bennett and Blacknell 2003):

$$S_R^{SL} = \begin{cases} \frac{h}{\cos \theta} + w_1 \sin \theta, & \text{if } \theta \geq \tan^{-1}\left(\frac{h}{w_1}\right) \\ \left(w_1 + \frac{h}{\tan \theta}\right) \sin \theta + h \cos \theta & \text{Otherwise.} \end{cases} \quad (4)$$

$$S_A^{SL} = w_2 \quad (5)$$

Figure 8a reports an example of a change detection map $\mathbf{M}_{SL}^{opt}$ obtained with the proposed method. As one can notice, in this example the change detection map $\mathbf{M}_{SL}^{opt}$ verifies the assumptions defined for the model presented in section “Building Backscattering Mechanism in Single Detected HR and VHR SAR Images,” which are (i) the detected regions of increase or decrease in backscattering at the building scale are homogeneous and (ii) the change detection map presents a reduced number of changes smaller than the size of buildings, i.e., changes that are not related to changed buildings (ω_{c4}) are filtered out. Hence, from $\mathbf{M}_{SL}^{opt}$ it is possible to identify the building radar footprints of new or destroyed buildings by locating the pattern of increase (ξ^+) and decrease (ξ^-) of backscattering (building candidates) and

by evaluating the matching between the proprieties of the building candidates with respect to the proprieties of new and destroyed building models described in section “Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images.” In detail, this task is based on two steps: first, the areas of change candidate to be associate to one of the classes ω_{c1} (demolished building), ω_{c3} (new buildings), or ω_{c3} (changes that have a size comparable to a building but do not present the typical pattern of full new/demolished buildings) are detected among all the backscattering changes highlighted in $\mathbf{M}_{SL}^{opt}$. The set of changed building candidates is denoted by $\Gamma = \{\gamma_1, \gamma_2, \dots, \gamma_H\}$. Then the matching between the expected backscattering behavior of changed buildings (presented in section “Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images”) and

Damage Detection in Built-Up Areas Using SAR Images, Fig. 8 Conceptual example of detection of a destroyed building (illumination source on the left). (a) M_{SL}^{opt} . The pixels associated to the classes of backscattering decrease (ξ^-) and increase (ξ^+) are reported in green and magenta, respectively. The idealized dismissed building radar footprint is drawn in dashed line. (b) In gray the bounding box of changed building candidate γ_h containing

the regions of change $\delta_1, \delta_2, \dots, \delta_8$ that form the candidate. (c) Illustration of the parameters S_I, S_D, l_I, l_D , and α , which are evaluated by the fuzzy rules described in Table 1 in order to check the matching between the candidate and the expected pattern. (d) Identified demolished building footprint (red continuous line) compared with the actual footprint (gray dashed line)

the characteristics of the changed building candidates is evaluated. This is done by considering the physical proprieties and the relation of the regions of change inside each candidate, i.e., $\Delta = \{\delta_1, \delta_2, \dots, \delta_K\}$. In order to properly model the uncertainty inherent in the process (that can be due, for example, to cluttered objects placed in front of buildings), fuzzy theory is used (Zadeh 1965). In Fig. 8 an illustrative example that depicts the detection process of the proposed approach is reported for the case of a demolished building. This example will be used in the paper to better illustrate the proposed approach. Figure 8b–d illustrates the process of the proposed building change detection stage for the case of a demolished building. In the following each step is described in detail.

The first step of the detection of individual collapsed building phase aims at detecting the set of changed building candidates $\Gamma = \{\gamma_1, \gamma_2, \dots, \gamma_H\}$. Ideally each changed building in M^{opt} is made up of regions of both increase and decrease in backscattering, whose total extension is comparable with the expected size of buildings. One simple and effective approach to identify the changed building candidates $\gamma_1, \dots, \gamma_H$ is to use a sliding window algorithm for each pixel in the image. Pixels within the moving window are taken and used to compute the detector output. In this work, the window is moved in M^{opt} from the left to the right by one pixel, and the number of changed pixels (labeled both as increase ξ^+ or decrease ξ^-) is counted. The process is repeated over five moving windows: four rectangular

Damage Detection in Built-Up Areas Using SAR Images,

Fig. 9 Windows used to derive the changed building candidates

moving windows showing different directions and a square window having the same area of the rectangular ones. This choice allows us to properly capture the most of the building orientations. The detector output is given by the window that results in the maximum value. The five windows are depicted in Fig. 9. The size of the windows $z_1 \times z_2$ is chosen according to the minimum size of the buildings in the considered scene in order to minimize missed alarms. Hence, let $\mathbf{M}_{\mathbf{W}_{i,j}^\beta}^{\text{opt}} = \left\{ \mathbf{M}^{\text{opt}} | \mathbf{M}^{\text{opt}} \subset \mathbf{W}_{i,j}^\beta \right\}$ be the set of pixels of $\mathbf{M}_{\text{SL}}^{\text{opt}}$ included in the window $\mathbf{W}_{i,j}^\beta$ centered at the pixel (i, j) $i = 1, \dots, I; j = 1, \dots, J$, with $\beta = 1, \dots, 5$ indicating the different windows. Let $\mathbf{C}$ be the image with size $I \times J$ that reports for each pixel $C_{i,j}$ an index of the size of the changes. $C_{i,j}$ is computed as the maximum on the five windows as follows:

$$C_{i,j} = \arg \max_{\beta \in 1, 2, \dots, 5} \left\{ \left| \mathbf{M}_{\mathbf{W}_{i,j}^\beta}^{\text{opt}} \in \zeta^+ \vee \mathbf{M}_{\mathbf{W}_{i,j}^\beta}^{\text{opt}} \in \zeta^- \right| \right\} \quad \forall \quad i = 1, \dots, I; \quad j = 1, \dots, J \quad (6)$$

where $|\cdot|$ indicates the cardinality of a set. The obtained index image $\mathbf{C}$ exhibits relatively high values when the sliding window contains a large amount of changes oriented in the same direction of the moving window. $\mathbf{C}$ exhibits relatively low

values when the sliding window contains a small amount of changes or the windows do not match the orientation of the change. Therefore, it is possible to detect the changed areas that can be associated in terms of size to the expected radar footprint of changed buildings by selecting the areas of $\mathbf{C}$ exceeding a certain threshold τ_C , thus obtaining the image $\overline{\mathbf{C}}$ as follows:

$$\overline{\mathbf{C}} \in \begin{cases} 1, & \text{if } \mathbf{C} \geq T_C \\ 0, & \text{otherwise.} \end{cases} \quad (7)$$

T_C is selected according to the expected minimum size of buildings $z_1 \times z_2$ in the investigated scene. The map $\overline{\mathbf{C}}$ represents the areas containing changes with size comparable or bigger than the minimum building size and therefore they belong to one of the classes $\omega_{c1}, \omega_{c2}, \omega_{c3}$. As one can notice, the pixels belonging to ω_{c4} are implicitly identified in this operation. From the map $\overline{\mathbf{C}}$ the set of changed building candidates $\Gamma = \{\gamma_1, \gamma_2, \dots, \gamma_H\}$ is extracted by calculating the connected components considering an 8-connected neighborhood. This is done by means of a flood-fill algorithm (Heckbert 1994). Each candidate γ_h ($h = 1, \dots, H$) contains a subset of regions $\Delta = \{\delta_1, \delta_2, \dots, \delta_K\}$ labeled as ξ_u, ξ^+ or ξ^- . The information associated to the kind of change is derived considering $\mathbf{M}_{\text{SL}}^{\text{opt}}$ in the areas delimited by the region γ_h . Figure 8b shows an example of

candidate γ_h that contains $\delta_k (k = 1, \dots, 8)$ regions for the case of a demolished building. In general the number of regions, k , may vary from 1 to K depending on the size and proximity of the changes. For the sake of clarity, in the next step of the individual collapsed building detection procedure, we assume that only two regions belonging to increase (i.e., $\delta^+ = \delta_k \in \xi^+$) or decrease (i.e., $\delta^- = \delta_k \in \xi^-$) occur inside a candidate. If more than two regions are present, all the combinations among the regions of increase and decrease are automatically analyzed by the proposed approach and the most reliable(s) selected.

In order to properly classify each collapsed building candidate according to the classes ω_{c1} , ω_{c2} , and ω_{c3} , the physical characteristics and the spatial arrangement of the pattern formed by the regions $\delta_k (h = 1, \dots, K)$ have to match with the four characteristics of the models of destroyed building discussed in section “[Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images](#).” The matching is tested exploiting four fuzzy rules called here: (i) completeness, (ii) proportionality of areas, (iii) equivalence of lengths, and (iv) alignment. These rules aim at associating a grade of membership to the changed building candidate for each of specific performed test. On the basis of the aggregate membership, the final classification decision is taken. In the following each rule is presented in detail. It is worth noting that the theoretical model of a new building is just alike to the model of a destroyed building but the orientation of the pattern is reversed (see section “[Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images](#)”). Therefore, the proposed method can detect collapsed buildings as well as new constructed buildings. Nonetheless, since the focus of this work is on the detection of collapsed building due to earthquakes, we concentrate in the following on this case.

Completeness

A pair of regions of increase and decrease is strictly needed to identify a destroyed building (ω_{c1}). The first rule evaluates the simultaneous

presence of δ^+ and δ^- inside the candidate γ_h . This is done by means of a crisp membership function μ_p that takes value 0 or 1 ($\mu_p(p) = \{0, 1\}$) depending on whether regions of increase and decrease are simultaneously present $\mu_p(p) = 1$ or not $\mu_p(p) = 0$.

Proportionality of Areas

This rule aims at verifying that the area δ^+ is not prevailing with respect to the area of δ^- and vice versa. The mathematical modeling of this rule depends on the parameters of acquisition and the size of the building as discussed in section “[Building Backscattering Mechanism in Single Detected HR and VHR SAR Images](#).” It can be effectively represented by a sigmoid membership function that evaluates the attribute $r_s = \min\{s_I/s_D, s_D/s_I\}$, where s_I and s_D indicate the areas of δ^+ , i.e., $S_I = |\delta^+|$, and δ^- , i.e., $S_D = |\delta^-|$, respectively. The sigmoid function is defined as follows:

$$\mu_{r_s}(r_s) = \frac{1}{1 + e^{-a_1(r_s - b_1)}}. \quad (8)$$

The constant $a_1 > 0$ tunes the slope of function and the constant $b_1 > 0$ locates the center of the function. Equation 8 returns values in $[0, 1]$. Figure 11 shows an example of sigmoid function. As one can notice this is in accordance with what it is expected: the smaller r_s is, the smaller the membership grade of the candidate.

Equivalence of Lengths

This rule aims at checking that the lengths of the regions δ^+ and δ^- in the azimuth direction are equivalent. This is done by identifying the extrema of the regions δ^+ and δ^- . To test the reliability of a candidate with respect to this criterion, the attribute $r_l = \min\{l_I/l_D, l_D/l_I\}$ (where l_I and l_D are the lengths in azimuth direction of δ^+ and δ^- , respectively) is used in the sigmoid membership function defined in Eq. 8 with appropriate parameters $a_2 > 0$ and $b_2 > 0$. Since the farther r_l is from 1 the smaller the membership grade of the candidate to be associated to a new/destroyed building, the slope of the sigmoid is steep and the center moved toward 1. Figure 8c illustrates

Damage Detection in Built-Up Areas Using SAR Images, Fig. 10 Example of a candidate γ_h that does not respect the equivalence of lengths. (a) M_{ST}^{opt} . The pixels associated to backscattering decrease (ζ^-) and increase (ζ^+) classes are reported in *green* and *magenta*,

respectively. (b) In *gray* the changed building candidate γ_h containing the regions δ_1 and δ_2 , which form the candidate. (c) Analysis of psychological proprieties and relations of the regions δ^+ and δ^-

Damage Detection in Built-Up Areas Using SAR Images,

Fig. 11 Example of sigmoid function $\mu_{r_s}(r_s)$ defined according to Eq. 8. The slope of the sigmoid is tuned by the parameter a_1 . b_1 defines instead the center of the sigmoid, i.e., $\mu_{r_s}(b_1) = 0.5$. In the represented case $a_1 = 15$ and $b_1 = 0.5$

an example of correct alignment between δ^+ and δ^- , whereas Fig. 10c depicts a case in which this rule is not satisfied.

Alignment

This rule is devoted to test the alignment of the entire pattern increase/decrease (which is made up of regions δ^+ and δ^-) with respect to the range direction. The alignment of the centroids of the regions of increase and decrease is considered, which is expected to lay on the same line. In detail, the absolute value of the angle α defined as the angle included by the line that connects the centroids of the regions δ^+ and δ^- and the SAR range direction is used in the equation of the

sigmoid Eq. 8. α ranges from $[-\pi/2, \pi/2)$. As expected, by imposing $a_3 < 0$ the larger is $|\alpha|$ the smaller is the membership grade of the candidate to be associated to a new/destroyed building. Figure 8c illustrates an example of correct orientation of the pattern increase/decrease, whereas Fig. 12c depicts a case in which this rule is not satisfied.

A summary reporting the description of each rule, the parameters, and the membership functions used to represent the rules is reported in Table 1.

The final decision on the label of the candidate is done according to the aggregated membership grade Y , which is calculated by combining the

Damage Detection in Built-Up Areas Using SAR Images,

Damage Detection in Built-Up Areas Using SAR Images, Table 1 Fuzzy rules used to classify γ_h as new building (ω_{c1}), demolished buildings (ω_{c2}), or change comparable to the size of a building but not related to fully new/demolished buildings (ω_{c3})

Rule	Parameter	Membership function
1. Presence of both regions δ^+ and δ^- (completeness)	p	$\mu_p(p) = \{0, 1\}$
2. Proportionality of areas of δ^+ and δ^- (proportionality of the areas)	$r_s = \min\left(\frac{s_l}{s_D}, \frac{s_D}{s_l}\right)$	$\mu_{r_s}(r_s) = \frac{1}{1+e^{-a_1(r_s-b_1)}}$
3. Equivalence of the lengths of δ^+ and δ^- along the azimuth direction (equivalence of the lengths)	$r_l = \min\left(\frac{l_l}{l_D}, \frac{l_D}{l_l}\right)$	$\mu_{r_l}(r_l) = \frac{1}{1+e^{-a_2(r_l-b_2)}}$
4. Alignment of the barycenters of the regions δ^+ and δ^- (alignment)	$ \alpha $	$\mu_{ \alpha }(\alpha) = \frac{1}{1+e^{-a_3(\alpha -b_3)}}$

four membership functions. Among the fuzzy aggregation methods presented in the literature in this work, the Larsen product implication (Larsen 1980) is used, i.e.,

$$\mathbf{M} = \mu_p \mu_{r_s} \mu_{r_l} \mu_{|\alpha|} \quad (9)$$

In this way, one low value among the individual membership grades yields the final result to be low regardless of the other values. The candidates that present a value of $\mathbf{M}$ greater than a user-defined threshold T_M are selected as fully demolished (ω_{c1}) if δ^- is appearing before than δ^+ in range direction. The others are classified as ω_{c3} (i.e., they are not fully demolished or new buildings). It is worth noting that T_M will be a small value since the algebraic product of value smaller than 1 results in value smaller than the

factors in Eq. 9. Nonetheless, the value of $\mathbf{M}$ obtained for each of these classes is representing a grade of reliability of the detection that can be used by the final users.

For each changed building candidate recognized as demolished building, the 8-extrema points (i.e., from top left to bottom right) of both the regions δ^+ and δ^- are calculated and used to find the smallest convex polygon that contains the two regions, i.e., the convex hull (see Fig. 8d). The computation of the convex hull is done using the Quickhull algorithm (Barber et al. 1996). This allows a generation of an envelope of a dismissed building radar footprint as much as similar to the ideal expected one. Once the building footprint candidate is classified a demolished building, reverting the equations 4 and 5, it is possible to obtain the actual size of the

building affected by the change, which is expressed in terms of $w_1[m] \times w_1[m] \times h[m]$ (see Fig. 3a).

Selection of the Parameters

In this section the role of the parameters used in the proposed approach is discussed in detail. The parameters can be divided into three groups: the first two groups are related to the building size and the third to the fuzzy rules. The first group includes s_r and S_A , which represent the size of the split used for the automatic thresholding procedure of the log-ratio image at the optimal building scale. As discussed in the paper, the split size is selected according to the average size of the building in the considered area. It is worth noting that the split-based thresholding approach has demonstrated to be tolerant to relative large variations of the selected split size with respect to the expected average size of buildings (see section “Dataset Description and Experimental Results”). The second group of parameters includes $N - 1$, z_1 , z_2 , and T_C that are related to the minimum size of the buildings in the investigated site. In general, the minimum size of buildings is driven by the typology of urban area (industrial or residential) and the zone of the world under analysis (e.g., typically buildings in US metropolis are larger than buildings in European towns). Nonetheless, by selecting large values of $N - 1$, z_1 , z_2 , and T_C , building candidates with size smaller than the chosen values can be excluded from the analysis. The third group of parameters is associated to the membership functions of the fuzzy rules. In detail the center of the sigmoids (regulated by b_1, b_2, b_3) represents the boundary situation that has half membership with respect to the theoretical model described in section “Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images,” while the slope (regulated by a_1, a_2, a_3) represents the flexibility of the rule to cope with clutter and noise. In the considered case the centers are fixed from the model, whereas the slope can be chosen considering real situations, e.g., urban density.

On the basis of this analysis and of our experimental results, we can conclude that the tuning

of the parameters to give as input to the proposed approach requires very basic prior information and is not critical.

Dataset Description and Experimental Results

On April 6, 2009, an earthquake of 6.3 moment magnitude scale (MMS) struck central Italy with its epicenter near L’Aquila (42°21’N 13°24’E). The earthquake caused damages to a relevant number of buildings in the city of L’Aquila: several buildings collapsed, and about 1,500 people were injured, and about 300 people died, making this event the deadliest earthquake to hit Italy since the 1980 Irpinia earthquake.

At the time of the earthquake, no SM images were available on the area of the event. Nonetheless, two SL (1-look, 0.5 m $\times$ 0.5 m pixel spacing, X-band) amplitude images (X_1 and X_2) acquired in HH-polarization in ascending orbit with 57–58° incidence angle and processed according to the standard processing level 1C (geo-coded ellipsoid corrected) acquired on April 5, 2009 and April 21, 2009, respectively. This is due to the fact that the COSMO-SkyMed constellation was operational for few years at the time and that only two out of the four satellites were fully operational. Therefore, the COSMO-SkyMed archive was just started to be populated with images. In order to assess the effectiveness of the proposed method, the SL images were used to generate a couple of images with a degraded resolution (pixel spacing of 2.5 m) that can be assimilated to SM images (I_1 and I_2). This was done by using a nearest neighbor interpolation without multilooking operations and thus obtaining in images with size of 5,000 $\times$ 5,000. In the following, we refer to these images as SM images. Moreover, in order to be consistent with the real relationship between the size of SM and SL images, in the following we considered SL images with size five times smaller than the obtained SM images, i.e., 5,000 $\times$ 5,000.

Figure 13a shows the map of the area covered by the two SM images. Figure 13b shows a false color composition of the two SM images

Damage Detection in Built-Up Areas Using SAR Images,

Fig. 13 L'Aquila: (a) map of the area covered by the SM COSMO-SkyMed images (Google). (b) RGB multitemporal composition of SM COSMO-SkyMed images (*red channel*, 21/04/2009, *green channel*, 04/05/2009, *blue channel*, 21/04/2009). (c) Hot spots map M_{SM} . In *red* and *blue* the most damaged regions. The size of these regions corresponds to the coverage guarantee by SL images

(red channel, 21/04/2009, green channel, 04/05/2009, blue channel, 21/04/2009) in which pixels with an increase in the value of backscattering appear in magenta tone, pixels with a decrease in the value of backscattering appear in green tone, and unchanged pixel in gray scale. It is worth noting that a relevant number of changes are present between the two acquisitions (see Fig. 13b). This increases the complexity of the detection of collapsed buildings.

In order to apply the proposed method, the two SM images were calibrated and coregistered (with sub-pixel accuracy), and the log-ratio image $\mathbf{I}_{LR}$ calculated. $\mathbf{I}_{LR}$ was filtered by applying recursively a 2D-SWT transformation and reconstructing considering only the low-pass information at the 4th level. From $\mathbf{I}_{LR}^{fil}$ the hot spots of changes were derived by applying the split-based thresholding. The size of splits $S_R^{SM} \times S_A^{SM} = 64 \times 64$ pixels (corresponding to $160 \times 160 \text{ m}^2$ on the ground) was selected according to average size of expected changes in the test site. The obtained map is reported in Fig. 13c. From $\mathbf{M}_{SM}$ and the cadastral map $Q = 4$, areas with extension comparable to SL images were selected to be further analyzed in order to detect the presence of collapsed buildings. Among these areas we selected a representative case (red box in Fig. 13c) to be used in the following in order to effectively illustrate how the proposed method for the detection of collapsed buildings works. Indeed, the considered area presents a relevant number of collapsed buildings, differently from the other areas that present changes due to the construction of refugee camps.

As described in the methodological part, the proposed approach for the identification of collapsed buildings firstly calculates the log-ratio image $\mathbf{X}_{LR}$. This was computed from the two calibrated and coregistered CSK SL images $\mathbf{X}_1$ and $\mathbf{X}_2$. In detail, the coregistration was performed with sub-pixel accuracy, and the radar brightness calibration was applied in order to render the two images comparable. From $\mathbf{X}_{LR}$ the set $\mathbf{X}_{MS} = \{\mathbf{X}_{LR}^0, \dots, \mathbf{X}_{LR}^n, \dots, \mathbf{X}_{LR}^{N-1}\}$ was computed by applying sequentially the 2D-SWT and the 2D-ISWT with an 8-length *Daubechies* filter. The impulse response of low-pass

decomposition *Daubechies* filter of order 4 is given by the following coefficient set:

$$\{-0.0105974, 0.0328830, 0.0308414, -0.187035, -0.0279838, 0.630881, 0.714847, 0.230378\}$$

The finite impulse response of the high-pass filter for the decomposition step can be computed by satisfying the properties of the quadrature mirror filters. The level $(N - 1)\text{th} = 3\text{rd}$, which gives a resolution of approximately 8 m, was selected as the optimum one. This allows to observe radar footprints of buildings as small as 8 by 8 m, which is compatible with the minimum size of building footprints in the considered scene. $\mathbf{X}_{LR}^3$ was thresholded according to the unsupervised split-based procedure described in section “[Detection of Damages \(Hot-Spots\)](#).” The split size was calculated starting from the average building size, which was estimated to be $w_1 \times w_2 \times h = 25 \times 20 \times 15 \text{ m}^3$. By substituting these values in Eq. 4 S_{SR} was obtained to be equal to 49.50 m in slant-range geometry. Since the CSK images are ground projected, S_{SR} was projected in ground range considering the reference incidence angle, i.e., 58° obtaining in this way $S_{GR} = 58.36 \text{ m}$. From the calculation and taking into account a pixel spacing in a range of 0.5 m, S_R results to be equal to 120 pixels. By applying Eq. 5 and considering a pixel spacing in azimuth of 0.5 m, S_A was estimated to be equal to 40 pixels. It is worth noting that the split-based thresholding technique has a relative high tolerance to the selection of the values of S_R and S_A . This was proven by a sensitivity analysis in which S_A was ranged from 20 to 60 pixels and s_r from 80 to 170 pixels. Despite the large range (about $\pm 1/3$ of the optimal selected size), the error on the estimation of the thresholds is small. Moreover, in all the cases the generated maps did not present any critical behavior and resulted in a very similar final detection of changed buildings. The obtained CD map $\mathbf{M}^{\text{opt}}$ highlighting the three classes ξ_u, ξ^+, ξ^- is reported in Fig. 14c. The detector described by Eq. 6 was then applied to $\mathbf{M}^{\text{opt}}$ in order to obtain the image C. With regard to the considered scene, it is expected that the minimum size of building footprint is 40×20 pixels. Therefore, the set of

5 windows reported in Fig. 9 were set to size $z_1 \times z_2 = 40 \times 20$ pixels in order to derive $\mathbf{C}$ (see Fig. 14d). A set of changed areas $\Gamma = \{\gamma_1, \dots, \gamma_{38}\}$ compatible with building footprint changes were derived by thresholding $\mathbf{C}$ with $T_C = 160$ (which corresponds to 20 % of maximum value of $\mathbf{C}$) and by applying a flood-fill algorithm. It is worth noting that both the window size and the threshold value were selected according to minimum size of buildings in the

considered area in order to limit the missed alarms. Each of the candidate areas was analyzed in order to detect the changed buildings. To this end the four fuzzy rules were automatically evaluated for each candidate γ_h , ($h = 1, \dots, 38$). Finally, for each building candidate that presents an aggregated membership T_M greater than 0.125, the building radar footprint was approximated by the convex hull containing the candidate. It is worth noting that T_M was selected in

D

Damage Detection in Built-Up Areas Using SAR Images, Fig. 14 (continued)

Damage Detection in Built-Up Areas Using SAR Images, Fig. 14 L'Aquila (Italy) dataset: (a) orthophoto acquired few days after the earthquake on April 2009 (Geoportale Abruzzo) and (b) RGB multitemporal composition of SpotLight COSMO-SkyMed images (R, 21/04/2009, G, 04/05/2009, B, 21/04/2009). The images are geo-projected according to the reference ellipsoid.

Actual range and the azimuth directions are reported in white arrows. (c) Change detection map M_S^{pt} obtained at the level $N - 1 = 3$. (d) Map showing the index of the size of changes C . (e) Changed building map overlapped to the RGB multitemporal composition of CSK data. (f) Cadastral map of the area (destroyed buildings are reported in red)

order to minimize the missed alarms. This is done by taking into account the definition of the membership functions and the aggregation strategy (i.e., algebraic product). In the present experiment $\mu_{rs} = \mu_{rl} = \mu_a = 0.5$ were selected as limit case, which results in an aggregate membership function $M = 0.125$. Figure 14e shows the final result. In the specific case, all the reconstructed building radar footprints have an aggregate membership function greater than 0.615. Table 2a reports the settings of the parameters used for the dataset of L'Aquila.

By comparing the changed building map with the false color composition of the multitemporal images (Fig. 14e), one can notice that the proposed approach can effectively detect the backscattering changes associated to disappeared buildings as described in section “Behavior of Changed Buildings in Multitemporal HR and VHR SAR Images,” which patterns present a decrease and increase in backscattering oriented near-to-far range (see Fig. 14e). From a quantitative point of view, Table 3 reports the number of

Damage Detection in Built-Up Areas Using SAR Images, Table 2 Parameters used in the experiments carried out on L'Aquila dataset

Parameter	Value
$N - 1$	3
S_R	120 pixels
S_A	40 pixels
z_1	40 pixels
z_2	20 pixels
T_C	160 pixels
a_1, b_1	10, 0.3
a_2, b_2	10, 0.5
a_3, b_3	$-10, \frac{\pi}{3}$
T_M	> 0.125

Damage Detection in Built-Up Areas Using SAR Images, Table 3 Performance of the proposed approach for L'Aquila dataset in terms of number of detected destroyed buildings, missed alarms, and false alarms

Total number of buildings	Detected destroyed (ω_{c1})	Missed destroyed	False destroyed
200	6	0	1

Damage Detection in Built-Up Areas Using SAR Images,

Fig. 15 (a–d) Zoom of the 6 buildings destroyed and correctly detected by the proposed method (Bing Maps, Microsoft Corporation). See Fig. 14 (f) for the correspondence of the buildings on the map. As one can notice the building was totally demolished after the earthquake

building radar footprints of demolished building detected by the proposed approach. Even though the dataset presents a relevant number of changes in the backscattering value, none of the actual demolished buildings (see Fig. 15a–d) were misdetected, and one of the building was wrongly

identified as totally destroyed (see Fig. 15e) even though it was half collapsed on itself. Figure 14f shows the positions of the destroyed buildings in the cadastral map obtained by transforming the geometry of SAR images to the geo-referenced cadastral map. The analysis confirms the high

accuracy of the proposed technique. It is worth noting that even though the density of buildings in the considered site is high, the proposed approach can effectively discriminate between demolished and standing buildings. This points out the high robustness of the proposed technique to the possible deviations from the adopted ideal model of changes. A similar analysis has been performed for changes that are not associated with buildings, i.e., ω_{c3} (yellow areas in Fig. 14d). The orthophotos point out that these changes are not associated to fully destroyed buildings but to the post-earthquake activities, e.g., emergency housing units or to partially damaged buildings. This confirms the effectiveness of the proposed method also in the detection of changes different from demolished buildings.

Summary

In this entry an approach for the rapid and accurate detection of damages in built-up areas after a catastrophic event using SAR data has been presented. SAR systems onboard of new generation SAR missions are able to acquire images with a geometrical resolution that varies from 5 m up to 1 m using two different operational modes called StripMap and SpotLight. By increasing the resolution the maximum ground coverage guaranteed decrease accordingly. In this entry we have proposed to jointly exploit these two acquisition modes in order to: (i) quickly identify the areas severely affected by the crisis event (i.e., hot spots) by analyzing large areas using data characterized by a high geometrical resolution (3–5 m) and (ii) accurately detect collapsed buildings inside each hot spot by analyzing small areas using data with very high geometrical resolution (1 m).

In the first phase of the proposed approach, the hot spots, which are areas with both a significant increase or decrease in the backscattering value, are detected from the SM images. Since the goal during this phase is to quickly identify the areas severely affected by the crisis event and not perform detection at a fine resolution, a comparison between the SM images with a log-ratio operator

and a de-noising operation based on the wavelet transformation was applied in order to obtain the hot spots. By exploiting the available prior information about the scene, i.e., cadastral maps, it was possible to define the regions to be further analyzed in order to detect the collapsed buildings.

The analysis at the level of single building is conducted in the second phase of the proposed approach by taking advantage of the theoretical behavior of collapsed building in HR and VHR SAR images. Hence, from this modeling it is known that destroyed buildings are identified as a pattern made up of an area of increase and decrease of backscattering with specific physical proprieties and a specific alignment. In order to extract the changes associated with increase and decrease in backscattering in the SL images, the proposed approach makes use of a multiscale representation of the multitemporal information. This allows a detection of changes at the optimal building scale. This means that changes smaller than the building scale are rejected, while changes related to building size are made homogeneous. This information is used to identify the candidates to be destroyed buildings. The building candidates are analyzed in order to properly detect the collapsed building by means of four fuzzy rules. The fuzzy rules are formulated by taking into account the ideal backscattering mechanisms that arise when a building appears or disappears between two acquisitions. The aggregated membership resulting from the application of the fuzzy rules makes it possible to identify the class of each building candidate (i.e., collapsed building, new building, or general change with size comparable to the building size but not related to new or destroyed building). Moreover, the membership value gives an indication of the reliability of the detected class. The proposed approach requires the tuning of some parameters that depend on the approximated size of the buildings in the investigated area. This is a prior information usually available and easy to include in the processing. It is worth remarking that after this tuning the method is completely automatic.

The proposed approach was tested using SAR data related to the earthquake of L'Aquila (Italy) in 2009 acquired by COSMO-SkyMed constellation.

The proposed method demonstrated to be effective in detecting all the demolished buildings with a high accuracy. In detail, only one building was misclassified over 200 present in the two datasets with no missed detection. This was possible because the high robustness of the proposed method to deviations from the ideal model considered for changed buildings. This robustness is due to both the use of adequate fuzzy rules and the intrinsic reliability obtained when working on the comparison of two images rather than on the modeling of building in each image.

As future development of this work, we plan to test the proposed approach considering SAR dataset related to other earthquakes. Moreover, we plan to engineer the proposed approach to be compliant with the cogent requirements of real emergency scenarios.

Archeoseismology

Introduction

Ever since man-made structures have been erected, earthquakes have left their marks on these constructions. The study of earthquake damage can contribute to multidisciplinary efforts to assess parameters of ancient earthquakes from archeological evidence (archeoseismology). Initially these studies were aimed at enriching earthquake catalogs; however, recent interest has been targeted to provide quantitative earthquake parameters and describe site effects (Galadini et al. 2006; Sintubin 2011).

Yet, there is widespread skepticism about whether structural damage to man-made constructions, displaced structures, and indications of repair can be used as earthquake indicators. Damage to ancient buildings is often hard to identify, even for experienced archeologists and engineers (Hinzen 2011). Here we offer a brief overview of earthquake-induced damages observed in ancient structures.

The fabric of the building (masonry, brick, rubble infill between retaining walls, built with or without mortar) has to be thoroughly understood before the analysis and interpretation of archeoseismological data can be undertaken (Rodríguez-Pascua et al. 2011). Each building material behaves differently under seismic loading; for example, dressed stone walls tend to be rather rigid, while rubble walls have limited elastic properties.

Following the seminal works of Karcz and Kafri (1978) and Stiros (1996), a multitude of studies have listed and illustrated supposed seismic-induced damage of ancient buildings, mostly from the Mediterranean. Korjenkov and Mazor (2003) and Marco (2008) discussed proven or supposed seismic origin of a rich variety of damage features, arranging them in groups of sliding and shifting blocks, fallen columns, chipped block corners, and fractured and deformed walls and floors. Rodríguez-Pascua and his team (2011) established a comprehensive classification of earthquake archeological effects, of which building damages form the most significant part. However, in-depth analysis, including physical or numerical modeling, is only available for just a

few types of structural damage (shifted blocks: Vasconcelos et al. 2006; dropped keystone: Kamai and Hatzor 2008; toppled columns: Hinzen 2009; Yagoda-Biran and Hatzor 2010; for a review, see Hinzen et al. 2011). Complex systems for classifying damage are available (e.g., the genetic approach of Rodríguez-Pascua et al. 2011), but here a simple, descriptive system is used based on the shape of the damage and on whether it involves a single block, multiple blocks, a single wall, adjacent walls, or a whole building.

Typology of Earthquake-Induced Damages in Ancient Buildings

Archeoseismology is far from being a science with established methods. However, a few considerations taken into account will help the researcher to recognize, analyze, and interpret earthquake damage in proper context. (1) The older a building, the higher is the chance it has been damaged by seismic activity. (2) Constructions made of meticulously dressed stone provide better records than coarsely worked stone. (3) Buildings neglected since an earthquake offer better record than repaired ones; however, the repair itself can be a source of information on previous structural damage. (4) The history of successive restoration and architectural modification must be understood before seismic analysis is undertaken. In general, ancient structures show no difference in deformation styles than those observed on masonry buildings due to modern earthquakes (Galadini et al. 2006).

Furthermore, finding only one piece of evidence cannot be considered conclusive (Stiros 1996; Mazor and Korjenkov 2001). The identification of different types of deformations, or the repetition of a certain deformation on numerous edifices of a settlement, can be considered as consistent with the occurrence of an earthquake, once other possible natural causes have been excluded (Galadini et al. 2006).

Damage Affecting a Single or Multiple Blocks

The vertical component of a seismic wave moves masonry blocks (ashlars or columns) rapidly up

Damage to Ancient Buildings from Earthquakes,

Fig. 1 Typology of earthquake-induced damages in ancient buildings. (a) Cracks/fractures within a block (second century AD Palmyra theater, Syria). Photo Kázmér #4281. (h) Displaced drums of masonry columns of the fifth-century BC Hephaisteion temple, Athens, Greece #1132. (i) Extruded portion of house wall. Bosra, Syria #4183

and down. The hammering effect of the upper block on the lower one yields cracks in either or both blocks (Fig. 1a). Penetrating cracks allow a chip, corner, or edge to be separated from the block (Fig. 1b). The direction of the crack is influenced by the lithology of the rock and shape of the block and by direction of hammering. Chipping is not to be confused with rounding

or peeling due to weathering as seismically broken chips have sharp edges.

Fractures cutting through two or more blocks are often oriented close to vertical, this being the weakest plane to resist bending forces (Fig. 1c). Fractures through individual blocks are more or less connected to each other, resulting from sudden seismic shaking.

Damage Affecting a Single Wall

Where blocks are arranged as walls, two categories of failure occur: *in-plane* failures, where loads act in the plane of the wall, and *out-of-plane* failures, where loads act at an angle to the wall's face.

The most common in-plane failures are *gaps* between shifted blocks (Fig. 1d), produced by lasting vibrations acting parallel to the wall. Cracks can develop across single or multiple blocks, even across whole walls. Brick walls display *diagonal cracks* near doors and windows. Masonry walls – dressed stones being significantly larger than bricks – generally do not display this feature.

Dropped keystones in arches are widely held to be the most reliable evidence of earthquake damage (Kamai and Hatzor 2008) (Fig. 1e). These are formed during horizontal shaking, if there is no significant vertical load (i.e., when higher parts of the building have already collapsed). In multistory buildings, arches in upper floors get damaged, while lower floors do not exhibit damaged arches. Significant vertical loading tends to hold masonry blocks together through high friction at interfaces.

Broken lintels (Fig. 1f) and thresholds occur widely. These features are not firm evidence for seismic shaking because differential settlement of walls due to inadequate foundation can also produce similar structures.

Common out-of-plane failures are *rotated blocks* (Fig. 1g), whose angle or rotation (clockwise or counter clockwise) reflects the direction of strong motion and the friction between adjacent blocks.

Displaced drums in rows of masonry columns (Fig. 1h) are products of either in-plane or out-of-plane seismic loads. Both shifting and rotation of drums occur. Historically, the observation of aligned, fallen monolithic columns has been used to infer directions of earthquake epicenters. However, this interpretation is erroneous, since column alignment in fallen structures can also be produced by heavy storms acting on deteriorated buildings (Ambraseys 2006).

Extruded blocks (Fig. 1i) indicate loads at a high angle to a wall. Displacement occurs along a more-or-less irregular pattern of masonry blocks

(mostly without through going fractures), reflecting the failure of the wall core. Masonry maintains coherence during displacement, indicating that not the mortar between blocks but mortar between wall and core maintains wall integrity.

The *arcuate collapse* of walls (Fig. 2a) is sign of loads acting at high angle to a wall that is confined (fixed) at both ends. Wall terminations (usually supported by cross walls) maintain their full elevation, while the free-standing middle part loses coherence and collapses during heavy vibration.

A *warped wall* is produced by out-of-plane loads acting at high angle to the wall (Fig. 2b). Warping can be to one or both sides. Thick walls made of Roman concrete can behave this way, while thin walls collapse in arcuate form (Fig. 2a). Generally, there is no change of wall geometry at foundation level.

A *V-shaped extrusion* near the top of a cylindrical building (Fig. 2c) indicates strong motion in the direction of extrusion.

Fallen walls lying on the ground are more-or-less preserving original coherence (Fig. 2d). A seismic load acting at a high angle to a wall can cause simultaneous collapse along the full length of the structure.

Damage Affecting Adjacent Walls

Triangular collapses in the corners of walls (Fig. 2e) are due to differential loading of perpendicular walls. Shaking in different directions at the same time shears off the masonry joints, allowing collapse of the weakened corner.

Simple *deformed geometrical structures deformed* (rectangular to parallelogram, circular to elliptical, etc.) (Fig. 2f). These features are hard to recognize, since deformations are subtle: parallels and right angles deviate a few degrees only (higher deformation would yield total collapse).

Whole Buildings

Tilted buildings are signs of uneven loading of subsoil (Fig. 2g). When seismic vibrations act on water-saturated soil, it loses coherence and behaves like a fluid. Building foundations – losing support during liquefaction events – suffer differential

Damage to Ancient Buildings from Earthquakes, Fig. 2 (a) Arcuate out-of-plane collapse in the market, Pompeii, Italy, repaired before the 79 AD eruption of Vesuvius, which buried the city. Photo: Kázmér #9266. (b) Warped northern side of the Valens aqueduct (Istanbul, Turkey). Completed in 368 AD, several subsequent earthquakes left their traces on the massive construction #0340. (c) V-shaped damage on the SW wall of the twelfth-century donjon of al-Marqab citadel, coastal Syria. The damage was inflicted by the 1202 earthquake (Kázmér and Major 2010) #4589. (d) Fallen masonry fence in the Roman city of Carnuntum (Deutsch-Altenburg, Austria) #5496. (e) Triangular missing parts

in corners of walls (al-Marqab citadel, coastal Syria) #4671. (f) Deformed circular dome of fourth- to eleventh-century Samtavro cathedral, Mtskheta, Georgia #1633. (g) Tilted Buddhist stupa (approximately fifteenth century) in Chiang Mai, Thailand. While a single tilted building does not indicate seismic origin, this stupa is one of 21 sites displaying tilting in the city (Kázmér et al. 2011) #3411. (h) Buttresses support the pillars of the Valens aqueduct in Istanbul, Turkey, completed in 368 AD #0335. (i) Valens aqueduct in Istanbul, completed in 368 AD. A brick arch was built to support the weakened stone arch after one of the frequent earthquakes in the region (Istanbul, Turkey) #0335

settlement, tilting, and collapse. Traces of total failure are mostly removed, but minor tilting – not affecting the use of the building – is often left unrepaired.

Very rarely a building – if built across an active fault – is sheared by fault movement. The displaced walls indicate the sense and cumulative offset of the fault since construction time. Walls are either displaced along a single fault (i.e., Vadum Iacob crusader tower, Israel: Ellenblum et al. 1998) or along a splay of faults, where the building maintains integrity, but the floor plan gets deformed (i.e., St. Simeon monastery, Syria: Karakhanian et al. 2008).

Repairs

Ruins of completely collapsed buildings are usually removed after an earthquake. Moderate damages are repaired on the spot, and additions, new walls, *buttresses* (Fig. 2h), *reinforced arches* (Fig. 2i), and other *supporting structures* can be identified as evidence of past earthquakes. Repairs are often built of different, often inferior material (Fig. 2i: brick arc supporting a stone arch), poorly fitted to masonry patterns, obstructing windows – these are features of repair following structural damage.

Study of damaged ancient buildings is a major source of evidence for past earthquakes: various seismic parameters (e.g., date, intensity, strong motion direction) can be assessed from a careful, critical study. However, before anyone jumps head-fast into archeoseismology, here is a cautionary note: attributing seismic origin to observed damage needs careful consideration and exclusion of all other potential causative agents (Ambraseys 2006).

Summary

Damage to ancient buildings is a major source of information about the parameters of past earthquakes (date, intensity, strong motion direction, just to name a few). Features to aid in the identification of seismic damage are briefly described

and illustrated and arranged in a simple, descriptive system. Deformations affecting single and multiple blocks of dressed masonry, single walls, adjacent walls, and whole buildings record evidence of seismic damage. Their recognition, careful analysis, and distinction from other types of damage (by aging, warfare, poor construction, etc.) need thorough and systematic study but provide much needed data on past earthquakes.

Introduction

While the seismic performance of a single building can be assessed by a detailed structural analysis, the assessment of the earthquake-induced damage to building stocks, i.e., hundreds or thousands of buildings within an urban or regional area, relies on the use of probabilistic fragility functions. Fragility functions represent the typical behavior of a group of buildings characterized by similar physical characteristics (i.e., structural, geometric, constructive, technological, etc.) in response to an earthquake. This entry describes how these functions are derived and how they are used to estimate damage scenarios for building stocks.

The modeling of earthquake-induced damage to buildings can be either probabilistic or deterministic or, since seismic risk assessment is a multi-step process, a combination of both. The benefit of probabilistic analysis is that they can account for the many uncertainties associated with seismic risk assessments of building stocks.

These include uncertainties in the quantification of seismic hazard, the identification of different building types and their characteristics within the building stock, the relationship between seismic hazard and physical damage, and the relationship between the physical damage and socioeconomic consequences.

In the case of seismic hazard definitions, there are uncertainties over the time, location, depth, and magnitude of future earthquakes. One approach to account for these is probabilistic seismic hazard assessment (PSHA) (Bommer 2002). In PSHA, maps of ground motion intensity are produced for a study area in which the values of the intensity measure at each location represent the ground motion that is predicted to occur on average once, within a specified return period, based on all possible earthquake sources. The earthquake consequences (e.g., damages, losses, or casualties) are computed for these ground motions. A feature of PSHA maps is that the evaluated ground motions are not necessarily predicted to occur simultaneously due to the same earthquake and therefore are not representative of a real earthquake. An alternative approach, which allows for more realistic representation of individual event, is to use a deterministic seismic hazard assessment (DSHA), i.e., to use scenario earthquakes. A single scenario earthquake does not account for the uncertainties in seismic hazard. However, the distribution of uncertainties can be represented by using a large-scale simulation technique such as Monte Carlo simulation or Latin hypercube sampling to undertake analysis for multiple scenario earthquakes, each with attributes determined probabilistically from the historic earthquake catalogue for the study area. In simulations such as this, where multiple potential outcomes are computed, statistical measures are needed to make inferences from the results.

There are also uncertainties in the relationship between seismic hazard and damage – two buildings of the same typology will not necessarily experience the same damage if exposed to the same ground motion due to inestimable factors such as constructive details, the age, and the maintenance history of each specific building.

A well-established tool used to relate building damage to seismic hazard probabilistically is the fragility function, commonly referred to as the fragility curve when presented graphically (e.g., Rossetto and Elnashai 2003). For a given level of ground motion intensity, fragility functions determine the probability that a building or a group of buildings will be in, or exceed, the i th damage state, d_i . The probabilistic relationship is commonly assumed to be a cumulative lognormal distribution. In this case, the fragility function can be expressed conditionally in the form of Eq. 1.

$$P[d \geq d_i | IM] = \Phi \left[\frac{1}{\beta_{di}} \ln \left(\frac{IM}{IM_{di}} \right) \right] \quad (1)$$

In Eq. 1, P is the exceedance probability for the i th damage state, IM is the ground motion intensity (e.g., peak ground acceleration), Φ is the standard normal cumulative distribution function, β_{di} is the standard deviation of the natural logarithm (dispersion) of ground motion intensity for the i th damage state, and IM_{di} is the median value of ground motion intensity at which the subject reaches the i th damage state. If different damage states are defined for the building or building class, then distinct fragility curves exist for each damage state with variation of the dispersion and median values of ground motion intensity. Therefore, the risk to a building or building class being assessed for multiple damage states will be represented by a set of fragility curves. Fragility curves define exceedance probabilities, but it is also desirable to know the probabilities that a building or building class will be in specific damage states. For a specified value of ground motion, these can be calculated from the intervals between the fragility curves, so the probability a structure is in the i th damage state is the difference between the exceedance probabilities for the i th damage state and the $i + 1$ th damage state (Eq. 2):

$$p_i = P[d \geq d_{i+1} | IM] - P[d \geq d_i | IM] \quad (2)$$

Figure 1 shows a set of fabricated fragility curves for a structure whose damage is defined

Damage to Buildings:

Modeling, Fig. 1 A fabricated set of fragility curves for a fictitious structural typology

by three damage states against peak ground acceleration. Although this form of fragility function has been widely adopted in academic literature and by risk assessment platforms, probabilistic functions do not necessarily have to assume a cumulative lognormal shape derived, as specified in section “[Assigning Damage to Buildings Based on Ground Motions](#).”

Six steps are necessary toward the modeling of building damage (Fig. 2). The first step is to classify the building stock under analysis, so that buildings that are expected to have a similar seismic performance are considered uniformly. To do so, it is necessary to select an existing building taxonomy or define an ad hoc building taxonomy, classify the building within the taxonomy, and enumerate the buildings in each one of the identified building classes. The second step is to define the appropriate scales for classifying damage to building structural and nonstructural components. The third step is to determine the appropriate earthquake hazard parameters against which damage should be evaluated. The fourth step is to generate the hazard scenarios (ground motions and land deformations) for which the building damage needs to be assessed. The fifth step is to identify the appropriate hazard-damage relationship and assign damage to buildings. The sixth step is to estimate the direct losses and functional impacts related to the earthquake-induced physical damage to buildings.

Classifying Buildings

The first step to predict expected damage to buildings, in the event of an earthquake, is to develop an accurate classification of the building stock. The purpose of classifying building stock is to group together buildings that can be expected to behave similarly, sustaining a comparable level of damage, when subjected to comparable levels of earthquake-induced ground shaking and deformation. To this aim, relevant data and information on the building stock should be collected. The following subsections provide a non-exhaustive overview of the steps that are needed to classify building stocks for seismic risk analysis purposes.

Building Taxonomies

Building classification framework for seismic risk analysis purposes, referred here as building taxonomies, groups buildings by their construction attributes, geometry, and age/maintenance conditions, among many other factors that can influence their seismic behavior. Furthermore, building taxonomies group buildings by their occupational and social function (i.e., residential, commercial, industrial). In fact, after the earthquake-induced physical damage to building, the number of casualties, the impact on content and machineries, the direct economic losses, and the business interruption aspects are strictly correlated with the building occupational and social function.

Damage to Buildings: Modeling,

Fig. 2 Suggested steps for assessing the earthquake-induced damage, and related functional impacts and direct losses, to buildings

D

This section will provide a literature review on different building taxonomies that have been proposed worldwide to classify building stocks according to their expected seismic performance and occupational function.

Early building taxonomies grouped building typologies according to their building material only. Table 1 reports, for example, the three building classes identified and defined by the Medvedev–Sponheuer–Karnik (MSK-64) macroseismic scale.

The need for a deeper diversification of building behaviors, when subjected to an earthquake event led to the definition of more

elaborated classification systems, such as the one proposed within HAZUS (NIBS 2003) for the United States and the European Macroseismic Scale EMS-98 (Grünthal 1998) for Europe, where, further to the material, consideration is given to primary parameters influencing the building damage, namely, (1) the building structural system, (2) the seismic design criteria (design code level), (3) the building height (low rise, mid rise, high rise), and (4) the nonstructural elements. Table 2 reports and compares HAZUS and EMS-98 taxonomies for unreinforced masonry and reinforced concrete buildings.

Damage to Buildings: Modeling, Table 1 Classes of buildings according to the MSK-64 macroseismic scale

A	Buildings with dry stone or clay, adobe, or mud walls
B	Buildings with brick walls, mortar blocks, masonry and mortar, stone block, timber frame
C	Buildings with metal structure or reinforced concrete

Recently, international projects and initiatives worldwide have developed and defined several further taxonomy systems aiming to represent the variety of building types around the world and the continued upgrading/modification of construction techniques. Pitilakis et al. (2013) proposed a modular and flexible taxonomy for classifying European masonry and reinforced concrete buildings, where buildings are classified according to some main categories, including the force-resisting mechanism (FRM), material of FRM, plan (regular or irregular), elevation (regular or irregular), cladding, detailing (ductile, non-ductile, with tie-rod beam, without tie-rod beam), floor system, roof system, height level, code level, and material. Subcategories (e.g., FRM, material of FRM, cladding characteristics, floor system material, roof system material, number of stories) were introduced for some of the aforementioned categories, to provide a more refined classification, when more accurate data are available for the building stock under analysis.

The Prompt Assessment of Global Earthquakes for Response (PAGER) project (Porter 2005) developed a comprehensive building taxonomy with an international coverage including structural types common in non-developed countries (i.e., adobe, clay, poor quality wood constructions). The Earthquake Engineering Research Institute (EERI) developed a World Housing Encyclopedia (WHE) (EERI 2000) collecting information related to housing construction practices in seismically active areas worldwide.

The Global Earthquake Model (GEM) developed a global building taxonomy aiming to represent all the building types around the globe (Brezev et al. 2013; Gallagher et al. 2013) by

Damage to Buildings: Modeling, Table 2 HAZUS (NIBS 2003) and EMS-98 (Grünthal 1998) classifications for unreinforced masonry and reinforced concrete buildings

	EMS 98	HAZUS
Unreinforced masonry	Rubble stone	Unreinforced masonry bearing walls (URM)
	Adobe (earth bricks)	
	Simple stone	
	Massive stone	
	U Masonry (old bricks)	
Reinforced concrete	U Masonry – RC floors	Concrete moment frame
	Reinforced concrete frame	
	Shear walls	
		Concrete frame with U Masonry infill walls

building on a comprehensive review of existing taxonomies (Charleson 2011) and on the findings from WHE. The effectiveness of existing taxonomy to represent building typologies worldwide was checked against different criteria (Porter 2005) aiming to define a simple, collapsible, and detailed taxonomy, international in scope, user-friendly, and able to distinguish differences in seismic performance, but extensible to future needs (e.g., to other natural hazards). Following this comprehensive and critical review, the Syner-G taxonomy (Pitilakis et al. 2013) was selected as the benchmark to define the GEM building taxonomy. The GEM taxonomy is organized as a series of expandable tables, describing various attributes at increasing levels of detail (up to 5 depending on the specific attribute). Fabricated examples of building taxonomy and building occupancy taxonomy are presented, respectively, in Tables 3 and 4.

Further to taxonomies for building structures, specific building taxonomies have been developed for nonstructural components and content (e.g., NIBS 2003; NIST 1999; Porter 2005). HAZUS (NIBS 2003) provided a classification for architectural components (e.g., veneer and

Damage to Buildings: Modeling, Table 4 Example of building occupancy taxonomy (Adapted from GEM taxonomy, Brezev et al. 2013)

Building occupancy class									
Unknown occupancy	Residential	Mixed use	Industrial	Agriculture	Assembly	Government	Education	Other occupancy type	Commercial and public
Level 1 attributes									
									Offices, professional/technical services ^a

finishes, cantilever elements and parapets, etc.), mechanical and electrical components (e.g., piping systems, elevators, etc.), and contents (e.g., file cabinets, bookcases etc.). NISTIR 6389 (NIST 1999) provided taxonomy for shell, interiors, services, equipment, furniture, and special constructions. Porter (2005) proposed an expendable and flexible taxonomy for nonstructural elements based on the review, combination, and improvement of the existing ones, including NISTIR 6389 (NIST 1999).

Building Inventories

A building inventory for seismic risk analysis purposes can be defined as an enumeration and characterization of the building stock under analysis according to the assumed taxonomy. Preparation of a building stock inventory is a critical part of a damage and loss estimation study and can be both time and resource consuming. A compromise needs to be sought between the time and cost required for higher-quality data on the building stock and the uncertainties arising from low-quality data. In order to obtain an inventory affordable both from the cost and the time point of view, it would be worth to collect, as a first step, all the already available data sources, while being conscious that these data are often overlapping and incomplete and that additional work might be required to reconcile multiple sources and missing data. Possible available sources, in order to built-up regional building inventory, are databases belonging to state, regional, and local authorities and private sector sources as well as inventory information arising from previous loss or available within seismic risk assessment tools or platforms (e.g., HAZUS NIBS 2003). Census data, for example, can provide aggregated data on the size, the number, and the age of residential buildings; conversely specific databases prepared, for example, for insurance purposes or for civil defense planning purposes can provide information on commercial and/or strategic buildings.

Further to available databases, there are different methods for collecting, processing, and archiving building inventory datasets. Currently, the most common and widely used approaches

(Tenerelli et al. 2013) include (1) ground screening procedures (e.g., field reconnaissance, sidewalk survey, street-front direct visual observation, interpretation of street-front photographs, etc.), (2) satellite-remote sensing approaches, or (3) a combination of ground screening procedures and satellite-remote sensing approaches. Ground screening procedures collect building attributes through direct observations, usually via (a) paper forms, ad-hoc formatted to quickly record relevant building characteristics and attributes (e.g., FEMA 154 1988), and (b) handheld equipment and software (e.g., tablet, phone) that enables user-defined electronic inventory data. For both the approaches, a critical aspect is the definition of the survey form that has to be coherent with the adopted building taxonomy (section “[Building Taxonomies](#)”) and with the adopted approach to assign damage to buildings as a function of the ground motion (section “[Assigning Damage to Buildings Based on Ground Motions](#)”). Furthermore, proper training of staff those performing the ground screening survey is essential since identifying structural types and other building attributes from the street can be challenging. Satellite and airborne remote sensing techniques may provide information on building stocks, e.g., building footprint and height information, in a timely and cost effective manner. However, these techniques must be closely calibrated to the particular region under study, and the analysis must be supported by expert judgment, coupled with some field reconnaissance.

Building Classification

The final aim of the building classification process is to identify and enumerate the buildings composing the building stock under analysis in each of the building types and subtypes considered by the assumed classification system. Although a lot of information sources on the building stock might be available at regional level, and further data can be collected (section “[Building Inventories](#)”), they might be insufficient for a direct classification of the building in terms of the construction types and occupancy classes identified by an assumed taxonomy (section “[Building Taxonomies](#)”).

	Slight (D_1)	Moderate (D_2)	Heavy (D_3)	Very heavy (D_4)	Collapse (D_5)
Masonry					
Reinforce Concrete					

Damage to Buildings: Modeling, Fig. 3 Damage grades for masonry and reinforced concrete buildings according to the EMS-98 macroseismic scale (Adapted from Grünthal 1998)

Therefore, inferences have to be established between larger groups of buildings (referred to as categories), recognized on the basis of more general information (such as land use patterns or building age) and building types or occupational classes. Inferences may take the form of “for masonry buildings built before 1919, 40 % belong to rubble stone typologies and 60 % are old brick masonry buildings.” The assumed inferences should be verified on the basis of the “expert opinion” of local engineers and building officials in order to verify that they reflect the construction features of the region. A ground screening procedures can be used to develop or check the inference rules, used to characterize the building stock into categories, as well to assess the accuracy of the available information.

Describing Building Damage

Earthquake-induced damage to building structures and nonstructural elements is usually described in a scale of multiple increasing damage states, also referred to as damage grades, from no damage to total collapse. The damage scale adopted in the HAZUS (NIBS 2003) platform, for example, accounts for four discrete damage states further to “no damage,” namely, minor damage, moderate damage, extensive damage, and collapse. In the European Macroseismic Scale EMS-98 (Grünthal 1998), the damage is represented in a discrete form through five-damage grades D_i ($i = 1 \div 5$), further to “no damage,” D_0 . Figure 3 represents the EMS-98 (Grünthal 1998) five-damage grades for masonry and reinforced building types. For each

damage grade, the EMS-98 scale provides a qualitative description of the expected physical impacts to structural and nonstructural elements.

Waiiles and Horner (1933) propose a five-damage state scale, where for some of the damage states, further to qualitatively describing the expected impacts to structural and nonstructural elements, an estimate of the damage extension is provided (Table 5). ATC-13 (1985) proposes a six-damage grade scale, plus a “none damage” (Table 5).

In order to estimate the functional impacts and consequences deriving from the earthquake-induced physical damage to buildings, functional impact scales are needed and a correspondence between physical damage grades/states and functional levels needs to be established. Vision 2000 (SEOAC 1995) proposes a five-level performance objective scale, where the following functional level/objectives for buildings are identified: fully operational, operational, life safety, and near collapse. Rossetto and Elnashai (2003) propose damage scales specific for reinforced concrete buildings (referred to as homogenized reinforced concrete, HCR) and a correspondence between physical damage states and performance objectives, namely, serviceability, damage control, and collapse prevention. The Applied Technology Council Report (ATC-21 1988) defines a tagging system, corresponding to a three-level scale, to be used for post-earthquake safety assessment aiming to identify buildings, which are safe to occupy (green tag) being undamaged or with light damage, temporarily unusable building (yellow tag) being affected by significant damage and requiring repairs before reoccupation, and unusable,

Damage to Buildings: Modeling, Table 5 Examples of damage and functional scales: comparison of damage grades and functional levels (Adapted from Rossetto and Elnashai 2003)

HRC	HAZUS	Vision2000	EMS-98	ATC-13	ATC-21	Wailes and Horner ^a
None	No damage	Fully operational	No damage (D ₀)	None	Green tag	A
Slight	Slight		Slight (D ₁)	Slight		
Light		Operational		Light		B
Moderate	Moderate	Life safe	Moderate (D ₂)	Moderate	Yellow tag	C
Extensive	Extensive	Near collapse	Heavy (D ₃)	Heavy		
Partial collapse			Very heavy (D ₄)	Major	Red tag	D
Collapse	Collapse	Collapse	Collapse (D _{G5})	Destroyed		E

^aA – Undamaged or minor cracking, no significant structural damage, minor veneer damage

B – Parapet failure or separation of veneer, major wall cracking, and interior damage

C – Failure of portion of exterior walls, major damage to less than 50 % of walls

D – Major damage to more than 50 % of walls

E – Non-repairable damage, demolition probably appropriate

dangerous buildings (red tag) being affected by heavy structural damage up to partial or total collapse, deemed in some cases for demolition. Table 5 presents few examples of damage scales and functional scales and compares their damage grades and functional levels.

Hill and Rossetto (2008) critically reviewed and compared building damage scales, identifying their potentialities and shortcomings for their use in seismic risk analysis and for loss assessment applications.

Selecting Appropriate Earthquake Hazard Parameters

The selection of earthquake hazard parameters, commonly referred to as intensity measure (IM), is a crucial step when assessing seismic risk for buildings. Performance, integrity, or damage of structures is, in fact, influenced by the intensity, frequency content, and duration of the ground motion (Weatherill et al. 2011a). The choice of a suitable IM should possibly account for the characteristics of the building stock analyzed (section “Classifying Buildings”) and the method used to predict the building performance, when subjected to seismic solicitations (section “Assigning Damage to Buildings Based on Ground Motions”). Physical–mechanical

parameters or qualitative parameters can be selected for the ground motion description.

Physical–mechanical parameters for the ground motion description aim to characterize the amplitude, the frequency content, and the duration of strong ground motion; some of them describe only one of these characteristics, while others may reflect several of them. In engineering application the most commonly used measure of acceleration for a particular ground motion is the peak horizontal acceleration, PHA, the maximum horizontal acceleration at the ground surface is also known as the peak horizontal ground acceleration. For most earthquakes, the horizontal accelerations is greater than the vertical acceleration, and thus the peak horizontal ground acceleration also turns out to be the peak ground acceleration (PGA). The PGA for a given component of motion is the largest (absolute) value of horizontal acceleration obtained from accelerogram of that component. By taking the vector sum of two orthogonal components, the maximum resultant PGA can be obtained. Horizontal accelerations have commonly been used to describe ground motions because of their natural relationship to inertial forces; however they do not provide any information about the dynamic behavior of a structure. This can be obtained by the use of response spectra. Response spectrum describes the maximum response of

a single-degree-of-freedom (SDOF) system to a particular input motion as a function of the natural frequency (or natural period) and damping ratio of the SDOF. The response may be expressed in terms of acceleration, velocity, and displacement. The maximum values of each of these parameters depend only on the natural frequency and damping ratio of the SDOF system (for a particular input motion). The maximum values of acceleration, velocity, and displacement are referred to, respectively, as spectral acceleration, S_a ; spectral velocity, S_v ; and spectral displacement, S_d . Note that for a SDOF system of zero natural periods the S_a would be equal to the PGA.

When adopting mechanical-based approaches for assessing damage to buildings (section “[Assigning Damage to Buildings Based on Ground Motions](#)”), S_a at the natural period of the structure and/or S_d should be the preferred IMs. Where a capacity spectrum method is used, the full spectrum is essential along with the definition of damping reduction factors (Weatherill et al. 2011a).

Differently from physical–mechanical parameters, the macroseismic intensity (I) is a qualitative description of the effects of the earthquake at a particular location, as evidenced by observed damage on the natural and built environment and by the human and animal reactions at that location. Thanks to its qualitative nature, macroseismic intensity is the oldest measure for earthquake impacts; I scales have been extensively used when adopting empirical-based fragility functions (section “[Assigning Damage to Buildings Based on Ground Motions](#)”). Different macroseismic intensity scales exist all over the world. Foulser-Piggott and Spence (2013) recently attempted the development of a uniform and worldwide recognized International Macroseismic Scale.

Weatherill et al. (2011a) provides a detailed and critical review of the recommended and more common and suitable intensity measures to use in seismic risk analysis for different types of buildings, including masonry, reinforced concrete, steel frame, and timber building types (Table 6).

Damage to Buildings: Modeling, Table 6 Most commonly used and recommended intensity measures (IMs) for seismic risk assessment of building stocks (Modified from Weatherill et al. 2011a)

Building type	Common IMs	Recommended IMs
Masonry	S_a , S_d , PGA, IEMS-98	S_a , S_d
Reinforced concrete	S_a , S_d , PGA, PGV, IEMS-98	S_a , S_d
Steel	S_a , S_d	S_a , S_d
Timber/wood	S_a , S_d , PGA, PGV	S_a , S_d

Generating Ground Motions

Two commonly recognized approaches exist for generating ground motions for seismic risk analysis purposes, namely, the deterministic seismic hazard assessment (DSHA) and the probabilistic seismic hazard assessment (PSHA). The DSHA considers each seismogenetic source separately and assume the occurrence of an earthquake of specified size at a specified location. PSHA combines the contributions from all the relevant seismogenetic sources pertinent to the region or urban area under analysis and allow for characterizing the rate at which earthquakes and particular levels of ground motions occur.

The maps of ground shaking generated by PSHA or DSHA approaches represent future possible “ground motion fields.” Ground motion fields, resulting from PSHA, provide for each location possible levels of ground shaking (logarithmic mean and residual) with the associated probability of being exceeded in a given time period, giving the rate at which particular levels of ground motion might occur (e.g., 10 % probability of being exceeded in 50 years, which correspond to a return period of 475 years). Results from a PSHA can be, as well, represented in terms of hazard curves, giving, at each location, the probabilities of exceedance within a given time period for a continuous range of ground shaking intensities. Ground motion fields obtained via DSHA represent at each site the level of ground shaking (logarithmic mean and residual) resulting from a single, deterministic

earthquake (e.g., the maximum historical event from a pertinent seismogenetic source or the maximum earthquake compatible with the known tectonic framework) at a specific location (e.g., the shortest distance from the source to the studied region, when the most unfavorable situation is considered).

It is well recognized that there is not a mutually exclusive dichotomy between DSHA and PSHA (Bommer 2002) and different approaches combining DSHA and PSHA have been proposed in the literature. Bazzurro and Cornell (1999) propose to select the event that is most likely to contribute to the hazard for a given intensity measure at a site, from the disaggregation of PSHA outputs. Bazzurro and Luco (2005) proposed the use of Monte Carlo simulations to reproduce a series of single earthquake scenarios within PSHA.

For PSHA, DSHA, and any combination of them, it is necessary, as a first step, to identify the potential seismogenetic sources pertinent to the region under analysis and characterize them in terms of locations, geometry, seismic activity, and possibly released energy. As a second step, it is necessary to represent the propagation of the ground motion by the use of a suitable ground motion prediction equation (GMPE). GMPEs, also referred to as “attenuation” relationships, are equations derived from observed strong motion records and provide a means for predicting the level of ground shaking (in terms of the desired intensity measure, e.g., PGA, PGV) and its associated uncertainty at any given site or location, based on the earthquake magnitude, source-to-site distance, local soil conditions, fault mechanism, etc. Due to the empirical nature of GMPEs, the ground motion at each site/location is estimated by the median, or logarithmic mean, of the ground motion plus two random variables, referred to as residuals. The residuals represent the aleatory variability, namely, the difference between the predicted and observed ground motions in the regression analysis, occurring intra-event, i.e., within a single event, and inter-event, i.e., between separate events (Douglas 2011). For this reason, when GMPEs are applied to a large area,

adjacent predicted ground motions do not correlate with each other and the resulting ground motion field is random. This is fine when dealing with spatially clustered analysis (i.e., analysis at a single site). Conversely, when the analysis is targeting spatially distributed building stocks and the simultaneous generation of ground motions at multiple sites is required, the ground motion field should be spatially correlated to more realistically represent the earthquake scenario. Crowley et al. (2008) found that the spatial correlation of ground motion field can significantly influence the outputs of a seismic loss analysis for distributed portfolios, when simulating a single earthquake scenario. A number of spatial correlation models are available in the literature. Weatherill et al. (2011b) present a comprehensive discussion and description of different methods to produce spatially correlated ground motion fields and to account for site amplifications.

Assigning Damage to Buildings Based on Ground Motions

The damage that might affect a building stock, when subjected to a seismic event, can be predicted via different approaches, including (a) actual damage observation, (b) expert judgment, (c) simplified mechanical and analytical models, or a combination of the three aforementioned approaches. Methods based on actual damage observations are derived statistically by processing the damage data from different earthquakes and by summarizing the outcomes in terms of (a) damage probability matrices (DPM) (e.g., Whitman et al. 1973, Table 7), (b) vulnerability curves (e.g., Giovinazzi 2005, Fig. 4a, c), or fragility curves (e.g., Rossetto and Elnashai 2003). A DPM is a matrix that summarizes the seismic damage that occurred in a set of buildings, represented as the statistical distribution for each of the damage grades D_i considered and for the different macroseismic intensities I . In other words, DPM expresses, in a discrete form, the conditional probability $p[D_i/T, I]$ to obtain a damage grade D_i due to an earthquake of

Damage to Buildings: Modeling, Table 7 Example of DPM, representing the probability of damage in percent by macroseismic earthquake intensity and damage states (Adapted from ATC-13 1987)

Damage state		Earthquake intensity				
		VI	VII	VIII	XI	X
1	None	95.0	49.0	30.0	14	3.0
2	Slight	3.0	38.0	40.0	30	10
3	Light	1.5	8.0	16.0	24	30
4	Moderate	0.4	2.0	8.0	15	26
5	Heavy	0.1	1.5	3.0	10	18
6	Major	–	1.0	2.0	4.0	10
7	Destroyed	–	0.5	1.0	2.0	3.0

macroseismic intensity I and for a defined building type T (Table 7). Examples of vulnerability and fragility curves obtained from the processing of damage observations are provided in section “Assigning Damage to Buildings Based on Macroseismic Intensities.”

Due to the inherent difficulty to retrieve comprehensive damage data for all the building types considered within an assumed taxonomy and for a complete range of damaging earthquake intensities, “hybrid” methodologies have been defined, where the available observed damage data have been completed with the use of different approaches, including numerical analysis, neural network system, fuzzy set theory, expert judgment, etc.

Expert-based methods imply the human judgment to completely replace the processing of observed data, leading to expert-defined *DPM* (e.g., ATC-13 1987) or score assignment procedures (e.g., ATC-21 1988; FEMA 154 1988).

Mechanical-based models for territorial scale analysis on classes of buildings can be defined on the basis of either traditional force-based procedures (e.g., capacity spectrum method implemented in HAZUS, in NIBS (2003), or in RISK-UE (2004)) or according to displacement-based designed approaches (e.g., Calvi et al. 2005). According to force-based procedures, the building performance is identified, within acceleration-displacement response spectra (ADRS) by the intersection point between the capacity curve of an equivalent nonlinear SDOF

system and the earthquake demand curve, adequately reduced to account for the inelastic behavior and energy dissipation capacity of the system (Fig. 4e). On the other hand, according to displacement-based approaches, the periods associated to the boundary of different limit states can be evaluated by the intersection between capacity curves, represented in terms of period displacement relationship, and the displacement spectrum demand curves, scaled by equivalent viscous damping factors. Other proposals for mechanical-based methods are based on the evaluation of collapse multipliers associated to alternative collapse mechanisms (e.g., Cosenza et al. 2005) or on the derivation of fragility curves directly from the results of extensive numerical analyses (e.g., Elnashai and Jeong 2005). The examples of an observed-based approach and a mechanical-based approach are summarized in the following subsections (sections “Assigning Damage to Buildings Based on Macroseismic Intensities” and “Assigning Damage to Buildings Based on Physical–Mechanical Ground Motion Parameter,” respectively). Despite being different for derivation and conception, a quantitative comparison and reciprocal calibration has been possible for these two specific methods, thanks to their closed-form formulations (Lagomarsino and Giovinazzi 2006). As a useful result, refinements of the methods based on numerical/experimental analysis were directly implemented into an equivalent macroseismic approach. Dually, the reliability of assumed force-based capacity curves was cross-validated on the basis of real observed damage data (Giovinazzi et al. 2006).

Assigning Damage to Buildings Based on Macroseismic Intensities

Combining classical probability theory and fuzzy set theory, a macroseismic approach was derived (Giovinazzi and Lagomarsino 2004; Giovinazzi 2005), based on the EMS-98 macroseismic scale definitions (Grünthal 1998) that summarize the damage observations following several European earthquakes. Numerical and complete *DPM* have been evaluated, in the range of damaging

Damage to Buildings: Modeling, Fig. 4 Macroseismic- and mechanic-based approaches: basic steps. Macroseismic: (a) medium, upper, and lower vulnerability curves for RC building types; (b, c) damage

probabilities p_k and fragility curves for RC types for $I_{EMS-98} = 9$ ($\mu_D = 2.25$). Mechanic: (d) elastic response spectrum; (e) evaluation of the performance point through capacity spectrum method; (f) lognormal fragility curves

EMS-98 intensities, I_{EMS-98} , and damage grades D_i ($i = 1 \div 5$), for the EMS-98 building classes and types (Table 2). Fuzzy set theory was effective to consider, within the proposed macroseismic approach, the epistemic uncertainties affecting the damage assessment and the building classification procedures (section “Classifying Buildings”). Upper and lower bounds of

the expected damage, as provided by the DPM_{EMS-98} , have been in terms of a mean damage grade, μ_D , defined as the mean value of the DPM_{EMS-98} damage distributions:

$$\mu_D = \sum_{i=1}^5 p_i i \quad 0 \leq \mu_D \leq 5 \quad (3)$$

where p_i is the probability of having damage of grade i , in the set of buildings.

The relationship between the mean damage grade, μ_D , and the intensity, $I_{\text{EMS-98}}$, has been represented in the form of $I_{\text{EMS-98}}-\mu_D$ damage curves (Fig. 4b) as

$$\mu_D = 2.5 \left[1 + \tanh \left(\frac{I + 6.25 * V - 13.1}{Q} \right) \right] \quad (4)$$

where Q is a ductility-based index and V is a vulnerability index, i.e., $V = V^* + \Delta V_m + \Delta V_r + \Delta V_s$, where V^* , the function of the building typology; ΔV_m , the behavior modification factor; ΔV_r , the regional vulnerability factor; and ΔV_s , the soil amplification factor. ΔV_s has been evaluated for different building types, class of height, and soil classes (Giovinazzi 2005), while the values of the V^* , ΔV_m , ΔV_r factors have been calibrated on the basis of observed damage data and expert judgment. A beta probability density function (Fig. 4b) has been assumed to represent the damage distribution around the mean damage grade μ_D . Fragility curves (Fig. 4c) defining the probability of reaching or exceeding each damage grade $P[d_i/I, (V, Q)]$ can be directly derived. Different scatter can be associated to the beta damage distributions depending on the level of the cognitive uncertainties and the reliability of the data used for the building classification (section “Classifying Buildings”).

Assigning Damage to Buildings Based on Physical-Mechanical Ground Motion Parameter

The mechanical method proposed in the framework of RISK-UE project (2004) is essentially a capacity spectrum-based method, similar to the one adopted by HAZUS (NIBS 2003) with few modifications including (1) the definition of capacity curves for non-designed European masonry typologies, accounting for the prevailing collapse modes, geometrical features, and mechanical and dynamic characteristics; (2) the definition of capacity curves for seismically designed buildings according to the Eurocode 8 (CEN 2003) and to older European design codes; and (3) the representation of the cognitive uncertainties. In order to facilitate the operative implementation, the mechanical method was defined with a closed-form solution (Lagomarsino and Giovinazzi 2006). Simplified bilinear elastic-perfectly plastic capacity curves were defined, given the yielding acceleration a_y , the fundamental period T , and the structural ductility capacity μ . Constant ductility inelastic response spectra were derived from a 5 % damped elastic response spectrum $S_{ae}(T)$ by means of a ductility-based reduction factor, $R\mu$. The displacement corresponding to the performance point S_d can thus be directly evaluated (Fig. 4e), without any further iteration as

$$S_{d*} = \begin{cases} \left[1 + \left(\frac{S_{ae}(T)}{a_y} - 1 \right) \frac{T_C}{T} \right] d_y & \text{if } T < T_C \quad \text{and } \frac{S_{ae}(T)}{a_y} > 1 \\ \frac{S_{ae}(T)}{a_y} d_y & \text{if } T_C \leq T < T_D \quad \text{and } \frac{S_{ae}(T)}{a_y} \leq 1 \\ \frac{S_{ae}(T_D) T_D^2}{4\pi^2} d_y & \text{if } T \geq T_D \end{cases} \quad (5)$$

where T_C and T_D define the onset of constant spectrum velocity and displacement range within the elastic response spectrum $S_{ae}(T)$ evaluated from deterministic or probabilistic hazard analyses (Fig. 4d).

Estimating Losses and Consequences Due to Building Damage

Earthquake-induced structural and nonstructural damage to buildings is the root cause for several

Damage to Buildings: Modeling, Table 8 Example of weight factors to assess consequences from earthquake-induced physical damage to buildings, referred to EMS-98 damage scale

Damage grade	Structural (S), nonstructural (NS)	w_k	MRD ^a	MRD ^b	MRD ^c	UFU ^d	S ^e
Slight (D1)	S = no, NS = slight	w_1	0.02	0.01	0.01	0	0
Moderate (D2)	S = slight, NS = moderate	w_2	0.1	0.1	0.1	0	0
Heavy (D3)	S = moderate, NS = heavy	w_3	0.5	0.35	0.35	0.40	0
Very heavy (D4)	S = heavy – NS = very heavy	w_4	1	0.75	0.75	1	0
Collapse (D5)	S = very heavy	w_5	1	1	1	1	0.3

^aMean damage ratio, derived from HAZUS (NIBS 2003)

^bMean damage ratio, derived and adapted from ATC-13 (1987)

^{c-e}Mean damage ratio, unfit for use buildings, severely injured from Bramerini et al. (1995)

losses and impacts. Consequences to buildings and their contents, direct economic losses (e.g., cost of repair/reconstruction of building structural or nonstructural elements or replacement of machinery and content), and consequences to inhabitants and building occupants can be estimated once the physical damage sustained by the buildings has been assessed. Different empirical correlations, translating structural and nonstructural damage into percentage of losses, are proposed by different authors and in the framework of different seismic risk analysis methods. These correlations apparently different can be, actually, represented according to a common formulation (Giovinazzi 2005).

Having the physical damage described in terms of a discrete damage scale (see Table 6 for some examples), the probability of having consequences p_c induced by an earthquake can be obtained as

$$p_c = \sum_i w_i p_i \quad (6)$$

where p_i is the probability of having a damage grade d_i and w_i is a weight factor, specifically defined for a specific consequence c and a damage grade i .

Table 8 summarizes weight factors for the evaluation of different consequences, including (a) the ratio between cost of repairing and cost of replacement defined as mean damage ratio, MDR ; (b) the number of buildings unfit for use, UFU ; and (c) the number of severely injured people, S .

The MRD weight factors in Table 8 are intended for the evaluation of economic losses due to the physical damage of buildings. Similar correlations can be derived for building contents and for business interruption.

Summary

Earthquake risk is a public safety issue that requires appropriate risk management measures and means to protect citizens, properties, infrastructures, and the built cultural heritage. The aim of a seismic risk analysis is the estimation and the hypothetical, quantitative description of the consequences of seismic events upon a geographical area (a city, a region, a state, or a nation) in a certain period of time. The effects to be predicted are the physical damage to buildings and other facilities, the number and type of casualties, the potential economic losses due to the direct cost of damage along with the indirect economic impacts (loss of the productive capacity and business interruption), the loss of function for lifelines and critical facilities, as well as social, organizational, and institutional impacts. The results provided by a seismic risk analysis could be regarded as helpful guidelines with respect to all the phases of risk management: during normal periods, during crisis periods, as well as in the recovery and post-emergency periods.

This entry has summarized the basic steps needed for modeling earthquake-induced damage to buildings at territorial or urban scale as

part of seismic risk analysis. It has described the importance and purpose of inventorying and classifying buildings. It has explained the importance of using an appropriate damage scale for classifying physical damage to building structural and nonstructural components or for describing the expected performance objectives for the buildings. The recommended parameters for describing seismic ground motion, against which damage should be evaluated, have been introduced. The use of either probabilistic seismic hazard assessment or deterministic scenario earthquakes or a combination of the two, to evaluate ground motions for building damage assessment, has been discussed. A concise review of hazard-damage relationships has been provided along with the presentation of the basic steps for the two of them, a macroseismic- and a mechanic-based approach, for which a closed-form formulation assures an easy computational implementation within seismic risk analysis tools and platforms. For both the methods, the classification of the building stock can be performed with data of different origin and quality (e.g., from data properly surveyed to statistical poor existent data), and a different uncertainty can be associated with the resulting damage evaluation depending on the quantity and on the consistency of dataset used. Finally, a simple approach for a first estimation of the expected direct economic losses and consequences to people, based on the estimation of the physical damage to buildings, has been presented.

Introduction

Infrastructure systems, also commonly known as *lifelines*, can be defined as the “systems or networks, which provide for the circulation of people, goods, services and information upon which health, safety, comfort and economic activity depend” (Platt 1991). Infrastructure systems include utility networks such as energy, water, telecommunications, and roads or discrete critical facilities such as hospitals, ports, and airports. They are crucial to the routine functioning of society and play an important role in emergency relief, reconstruction, and recovery after an earthquake.

Infrastructure systems are made up of different types of components, including “point”

components, which include facilities used for generation, storage, treatment, or redistribution of a utility, and linear components that connect these facilities acting as conduits for the distribution and transmission of the service. Earthquake-induced physical damage to infrastructure generates direct losses due to the cost of repairs to these components. Furthermore operational failure resulting from physical damage diminishes the capacity of the infrastructure system to provide services to its consumers, resulting furthermore in indirect losses due to business interruption and subsequent long-term economic impacts.

The modeling of earthquake-induced damage can be either probabilistic or deterministic or, since seismic risk assessment is a multistep process, a combination of both. The benefit of probabilistic analysis is that they can account for the many uncertainties associated with seismic risk assessments of infrastructure. These include uncertainties in the quantification of seismic hazard, the relationship between seismic hazard and component damage, and the relationship between component damage and component functionality.

In the case of seismic hazard, there are uncertainties over the time, location, depth, and magnitude of future earthquakes. One approach to account for this is probabilistic seismic hazard assessment (PSHA) (Bommer 2002). PSHA maps of ground motion intensity are produced for a study area in which the values of the intensity measure at each location represent the ground motion that is predicted to occur on average once within a specified return period based on all possible earthquake sources. The earthquake consequences (e.g., damages, losses, or casualties) are computed for these ground motions. A feature of PSHA maps is that the evaluated ground motions are not necessarily predicted to occur simultaneously due to the same earthquake and therefore are not representative of a real earthquake. An alternative approach which allows for more realistic representation of individual events is to use scenario earthquakes. A single scenario earthquake does not account for the uncertainties in seismic

Damage to Infrastructure: Modeling, Fig. 1 A fabricated set of fragility curves for a fictitious structural typology

hazard. However, the distribution of uncertainties can be represented by using a large-scale simulation technique such as Monte Carlo simulation or Latin hypercube sampling to undertake analysis for multiple scenario earthquakes, each with attributes determined probabilistically from the historic earthquake catalog for the study area. In simulations such as this where multiple potential outcomes are computed, statistical measures are needed to make inferences from the results. The simulation approach to loss estimation is common in catastrophe modeling in the insurance sector (Bazzurro and Luco 2005).

There are also uncertainties in the relationship between seismic hazard and damage – two structures of the same typology will not necessarily experience the same damage if exposed to the same ground motion due to inestimable factors such as the maintenance history of a structure. A well-established tool used to assess this risk is the fragility function (or fragility curve when presented graphically) and relates damage to hazard probabilistically (Rossetto and Elnashai 2003). For a given level of ground motion intensity, fragility functions determine the probability that a structure or component will be in, or exceed, the i th damage state, d_i . The probabilistic relationship is commonly assumed to be a cumulative lognormal distribution. In this case the fragility function can be expressed conditionally in the form of Eq. 1:

$$P[d \geq d_i | IM] = \Phi \left[\frac{1}{\beta_{d_i}} \ln \left(\frac{IM}{IM_{d_i}} \right) \right] \quad (1)$$

In Eq. 1, P is the exceedance probability for the i th damage state, IM is the ground motion intensity (e.g., peak ground acceleration), Φ is the standard normal cumulative distribution function, β_{d_i} is the standard deviation of the natural logarithm (dispersion) of ground motion intensity for the i th damage state, and IM_{d_i} is the median value of ground motion intensity at which the subject reaches the i th damage state. If different damage states are defined for a component, then distinct fragility curves exist for each damage state with variation of the dispersion and median values of ground motion intensity. Therefore, the risk to a component being assessed for multiple damage states will be represented by a set of fragility curves. Fragility curves define exceedance probabilities, but it is also desirable to know the probabilities that a structure will be in specific damage states. For a specified value of ground motion, these can be calculated from the intervals between the fragility curves, so the probability that a structure is in the i th damage state is the difference between the exceedance probabilities for the i th damage state and the $i + 1$ th damage state. Figure 1 shows a set of fabricated fragility curves for a structure whose damage is defined by three damage states against peak ground acceleration. Although this form of fragility function has been widely adopted in academic literature and

by risk assessment platforms, probabilistic functions do not necessarily have to assume a cumulative lognormal shape. Moreover, fragility functions can also be deterministic, exemplified by the repair rate functions used to evaluate damage to pipelines (Kakderi and Argyroudis 2014).

Seven steps are necessary toward the modeling of infrastructure damage. The first step is to produce taxonomy of infrastructures and their constituent components so that elements that are expected to behave similarly are considered uniformly. The second step is to define the appropriate scales for classifying damage of each component. The third step is to determine the appropriate earthquake hazard parameters against which damage should be evaluated. The fourth step is to generate the appropriate ground motions necessary to assess damage. The fifth step is to identify the appropriate hazard-damage relationship and assign damage to each component based on the ground motion. The sixth step is to assess the performance of the whole infrastructure system based on the damages that have been assigned to each component within it. The final step is to model the restoration times for infrastructure components, which is necessary to evaluate indirect losses from business interruption. This process is summarized as a flow chart in Fig. 2, which shows the steps involved in the risk assessment of a single infrastructure system due to a single earthquake.

Classifying Infrastructure

The purpose of classifying infrastructure into taxonomy is to group together elements that can be expected to behave similarly following an earthquake. While buildings are discrete structures which can be grouped together based on certain structural characteristics (e.g., material, geometry, year of construction), infrastructure systems are made up of different components whose differences are based on their function as well as their constructive characteristics. As such classification of infrastructure systems is in two parts: firstly, identification of the different

components that exist in the system and, secondly, identification of the typologies of that component.

For example, an electric power network may comprise three components: generation plants, substations, and conduits. Each of these serves a different function in the system. Generation plants are responsible for production of electric power, conduits transport the electricity from one location to another, and substations allow for voltage change and/or redistribution. Then for each of these components there are different typologies, relating to structural or operational attributes. Electrical conduits, for example, can vary based on their position (overhead lines or underground cables), their insulation material, or their size. Substations may vary by load capacity or voltage.

For infrastructure systems it is not just the damage to the individual components that is important but also how the whole system consequently performs, e.g., is a water supply system able to supply water in sufficient quantity at adequate pressure to all consumers? While damage informs direct losses, system performance is needed to inform indirect losses as well as emergency management decision-making. To ensure that system performance can be properly evaluated, classification of a single infrastructure system should therefore include all constituent components whose damage condition may affect service provision. It is essential also to understand the connections between these components and their spatial distribution relative to urban populations, since some components will be more critical than others in terms of their impact on system performance. Another feature of infrastructure systems that does not apply to building risk assessments is the interdependency between systems, for example, the reliance of the water supply system on electricity in order to power pumping stations. It is good practice to identify and document these connections in order to fully understand the potential risk to an infrastructure. Although it is possible to model all infrastructure systems as a single composite system of systems, this is computationally intensive. There is a growing field of research investigating

Damage to Infrastructure: Modeling,
Fig. 2 Procedure for assessing the risk to a single infrastructure system due to a single earthquake

modeling methods that can account for such interdependencies quantitatively, but at present little of this has been adopted in risk management practice.

Table 1 shows a fabricated example of infrastructure taxonomy, including some important infrastructure systems, their key constituent components, and component attributes. The component attributes are the descriptors that could be used to group components into distinct typologies. Components can sometimes be pieces of equipment housed inside a building. In this case

the attribute “seismic design level” refers to whether the building is seismically designed or whether the component is secured. Sometimes components are made up of a systemic arrangement of smaller subcomponents. In this case “seismic design level” refers to whether or not these subcomponents are secured to protect them from ground shaking.

An inventory is an enumeration of the components and facilities in each of the typologies considered by the assumed taxonomy. Preparation of an inventory for infrastructure can be difficult

Damage to Infrastructure: Modeling, Table 1 An example infrastructure system taxonomy

Infrastructure system	Components	Component attributes
Electric power	Generation plants	Capacity, seismic design level
	Substations	Voltage, seismic design level
	Cables	Material, size
Potable water	Wells	Seismic design level
	Water treatment plants	Capacity, seismic design level
	Pumping stations	Capacity, seismic design level
	Storage tanks	Elevation, material, geometry, quantity of contents, seismic design level
	Pipelines	Material, joint type, age, diameter
Waste water	Lift stations	Capacity, seismic design level
	Treatment plants	Capacity, seismic design level
	Pipelines	Material, joint type, age, diameter
Natural gas	Pipelines	Material, joint type, age, diameter
	Compressor stations	Capacity, seismic design level
Fuel	Refineries	Capacity, seismic design level
	Pumping stations	Capacity, seismic design level
	Storage tanks	Elevation, material, geometry, quantity of contents, seismic design level
	Pipelines	Material, joint type, age, diameter
Telecommunications	Central offices	Seismic design level
	Cables	Material, size
Highways	Roadways	Importance level
	Bridges	Structural system, material, age, geometry, seismic design level
	Tunnels	Construction method, geometry, local geology
	Embankments	Height, soil type

since attributes cannot always be identified by simple visual inspection, and in many cases the components are not visible (e.g., buried pipelines). The inventory should therefore be prepared by collecting data from available sources. In the case of infrastructure, however, usually the only source is the system operator. To protect commercial interests and due to concerns over security, this type of information is not usually available in the public domain to a high level of detail, and so depending on the granularity of the modeling exercise, it may only be feasible to work in partnership with infrastructure owners.

Some infrastructure components may need to be assessed in more detail individually because of their criticality or damage consequences. An example of this would be a nuclear power station within an electric power network, since the consequences of damage to nuclear power stations have the potential to be extremely serious over

a wide geographical area. If such analysis of an infrastructure component is required, then the arrangement of its constituent subcomponents may also need to be documented in the taxonomy.

Describing Infrastructure Damage

The damage scales used to model infrastructure damage vary depending on the type of component being assessed. All networked infrastructures can be represented as an arrangement of “point” components, also known as *nodes* and linear components, also known as *edges*. The nodes are the facilities within the infrastructure system and the edges are the components that connect the facilities and connect consumers (or end users) to the service. Figure 3 illustrates a small fictitious electric power transmission system represented diagrammatically as a network, where the

Damage to Infrastructure:

Modeling, Fig. 3 A schematic diagram of a fictitious electric power transmission network. The network would continue to divide into further branches as power is distributed to customers and voltage is stepped down

D

generation plant and substations are nodes and the overhead lines and buried cables are edges. In a potable water system, the nodes could be wells, treatment plants, or pumping stations and the edges would be pipelines. This classification of nodes and edges determines the way in which damage is described. Damage to edges is usually described per unit length, whereas damage to nodes is described for the whole component.

Damage to infrastructure nodes can be described either in terms of physical damage or operational failure. Where components are housed inside buildings, it may be necessary to separately assess the operational state of the equipment and physical damage to the building. For infrastructure components housed in buildings, it is possible for the structure to be significantly damaged yet the component is fully operational as none of the equipment is damaged. Conversely it is possible for the structure to be sound yet the component does not function because equipment inside has been damaged. The purpose of infrastructure is to provide a service to consumers, and so while assessing structural damage is important for calculating direct losses, it is also important to assess the operability of the component after an earthquake, noting that the two do not necessarily correlate.

Damage to buildings is usually described in a scale of multiple increasing damage states from

no damage to total collapse. The damage scale adopted in the HAZUS (NIBS 2003) platform, for example, accounts for no damage, minor damage, moderate damage, extensive damage, and collapse. For buildings it is desirable for damage scales to correspond to damage limit states including serviceability, damage control, and collapse prevention (Rossetto and Elnashai 2003). Damage scales for equipment should relate to its operational state or functionality since this is most critical for evaluating indirect losses. The difficulty in identifying distinct physical damage states for equipment means that damage to equipment is often assessed only in terms of its operational state. The post-earthquake functionality can be expressed simply in binary terms, i.e., whether the equipment is operational or has failed, which is equivalent to a single damage state, or a set of fragility curves may be used to represent varying degrees of functionality.

While damage to infrastructure nodes is usually classified qualitatively, damage to infrastructure edges can be assessed quantitatively. The only type of infrastructure edge that has been studied extensively in terms of seismic risk is pipelines, which exist in water supply, waste water, natural gas, and fuel delivery networks. Fragility curves are not used to assess risk to pipelines, and instead the common parameter for pipeline damage is the repair rate. The repair

rate is a deterministic calculation of the mean number of damages that the pipeline is expected to experience per unit of length, usually per kilometer. For the damages, no distinction is made between breakages or leakages. The relationship between repair rate and earthquake hazard commonly follows a power law relationship although more complex functions do exist (Kakderi and Argyroudis 2014). Most repair rate functions have been derived empirically, and the typical form of a power law repair rate function is shown in Eq. 2, where RR is the repair rate, IM is the earthquake hazard parameter, and a and b are coefficients determined using some regression technique (ALA 2001):

$$RR = a \times IM^b \quad (2)$$

To account for different material properties or soil conditions, the repair rate function may include additional multiplying factors which vary according to attribute, or a set of functions may be proposed for different conditions.

Selecting Appropriate Earthquake Hazard Parameters

Ground shaking hazard is commonly represented by either peak ground acceleration (PGA) or peak ground velocity (PGV). It is usual for above-ground components such as substations to be assessed against PGA, while buried components such as pipelines are assessed against PGV. Various studies (e.g., Isoyama et al. 2000; O'Rourke et al. 2001) have shown that pipeline damage correlates better with PGV. This may be because PGV relates to ground strains, which are more relevant to buried components, whereas PGA relates to inertia forces, which are more relevant to above-ground structures (Pineda-Parros and Najafi 2010).

Infrastructure risk can also be assessed for earthquake-induced ground deformation hazard such as liquefaction or lateral spreading, although this is less common since the prediction of permanent ground deformation is more complex. There are very few predictive relationships for

permanent ground deformation (Tromans 2004), and those that do exist often require detailed geotechnical data (Bird et al. 2006). While this may be feasible for single-point analysis such as for buildings, it is not always practical to obtain this data across a spatially distributed infrastructure system. Furthermore, even if ground deformation can be predicted, there are very few relationships that can then be used to relate this to infrastructure damage (Bird and Bommer 2004).

Generating Ground Motions

For modeling building damage, ground motion intensities are usually evaluated by probabilistic seismic hazard assessment (PSHA) to account for the uncertainty in the attributes of potential earthquakes over the assessment period. However, this method is not suitable for spatially distributed infrastructure systems. Since the ground motion intensity map produced by PSHA is a composite statistical representation of multiple possible earthquakes, the ground motions do not replicate those that might be produced by a single real earthquake. However, a true earthquake representation is important for infrastructure systems. In order to evaluate the performance of a system after an earthquake, it is necessary to know the damage state and functionality at each component simultaneously and hence also the ground motion at each site simultaneously. Because PSHA ground motions are usually evaluated for long return periods, they are conservative compared to the ground motions that would be generated by most possible earthquakes in the region. This increases the likelihood that the model will predict component failures, leading to larger reductions in system performance and a conservative estimation of indirect losses accrued.

Infrastructure systems require a method that can evaluate seismic hazard simultaneously over a large area and should therefore be modeled using scenario earthquakes, with Monte Carlo simulation or a similar technique used to account for the distribution of potential earthquake

attributes. In the Monte Carlo simulation, multiple earthquake events are simulated, the attributes of which are assigned randomly but probabilistically based on data from historic earthquakes in the region. The result is a hybrid between deterministic and probabilistic hazard analysis (Bommer 2002). Damage, operational performance, and losses are assessed for each event, generating a distribution of impacts. Statistical measures can be used to make inferences from the distribution, ranging from very simple measures such as median or percentile values to more complex statistical techniques. An important criterion for this type of analysis is that the number of events in the simulation is sufficiently large to represent the likely distribution of attributes.

For scenario earthquakes, ground motions can be evaluated using ground motion prediction equations (GMPEs). However, since GMPEs are derived empirically with resulting uncertainties, GMPEs contain a deterministic part, which calculates the median value of ground motion and added to this are one or two random variables representing the variability that occurs within a single event (intra-event) and between separate events (inter-event) (Douglas 2011). Therefore, when GMPEs are applied to a large area, adjacent ground motions do not correlate with each other and the resulting ground motion map is random. This is not a problem for analysis at a single site, but for analysis of spatially distributed systems, the requirement for simultaneous ground motions at multiple sites means that the ground motions must be spatially correlated to more realistically represent an earthquake scenario. It is possible to generate a spatially correlated ground motion map by ignoring the random variables, hence using only median ground motions, or assuming a constant value for the random variables. This approach is straightforward, but the distribution of uncertainties is then not represented. More complex geostatistical methods can be used to empirically determine the spatial correlation of ground motions in a region based on historic data and apply them to simulated earthquake scenarios. These are not discussed here but one method for

producing spatially correlated ground motion fields is included in the European seismic risk platform, SYNER-G, and is described by Weatherill et al. (2014).

Assigning Damage to Infrastructure Components Based on Ground Motions

D

The method for assigning damage to infrastructure components for a scenario earthquake varies depending on whether the relationship between hazard and component damage is defined by a probabilistic fragility function or by a repair rate function. For a component whose damage is defined by a fragility function, described below are two approaches that can be applied to ensure the assignment of damages to each component reflects the distribution of damages defined by the fragility function.

The taxonomy produced in the first step of modeling process has already defined and grouped the different typologies of all components by attributes. The first method for damage assignment involves subdividing the typologies further by grouping together the occurrences of each typology that are exposed to the same ground motion. If there are a large number of components, it may be possible to only group occurrences exposed to exactly the same level of ground motion, but if they are few in number, then it may be necessary to define ground motion intervals and group together the occurrences that fall within the same interval. With the components grouped by attributes and ground motion, it is possible to assign damage states to all components that reflect the probabilistic distribution of the relevant fragility functions at the corresponding ground motion level. So, for example, if the fragility function defines that 20 % of a particular component typology experiencing a PGA of 0.5 g should fail, then 20 % of the components of that typology being exposed to 0.5 g should be assigned to the “failure” damage state. This is repeated for each damage state and then for groups of the same typology exposed to different ground motions. The whole process can then be repeated for other

typologies, resulting in a numerical count of the different component typologies in each damage state.

To measure system performance in infrastructure systems, however, it is important to know not just how many components of a particular typology are damaged but also specifically which ones, since different occurrences of a component will have different systemic influence either because of varying service area sizes or different levels of local network redundancy. An example might be an electric power network with two generation plants, one which serves 75 % of a city and another which serves the other 25 %. This method for damage assignment might tell us that one of these has failed but not which one, with the two possibilities producing very different outcomes in terms of system performance impacts. It is possible to assign the damage states to specific components on a random basis, but in that case all assignment permutations should be modeled for each scenario earthquake to ensure that the distribution of potential impacts is represented. The system performance and loss calculations should then also be computed for each of these permutations.

An alternative method for damage assignment from fragility functions involves modeling each component individually rather than in groups. The first step in this procedure is to assign a random number to each component by sampling from a uniformly distributed variable, u , where $0 \leq u \leq 1$. The random number is then compared to the damage state exceedance probabilities defined by the fragility function at the corresponding ground motion level for that component. The condition described in Eq. 3 can then be used to assign the damage state. In Eq. 3, u_j is the sampled random variable for component j and P is the exceedance probability of i th damage state, d_i , for component j at the corresponding ground motion intensity, IM . So the component is assigned to a specific damage state if the sampled random number is less than or equal to the exceedance probability for that damage state but greater than the exceedance probability for the next most damaging state.

$$P[d \geq d_{i+1}|IM] < u_j \leq P[d \geq d_i|IM] \quad (3)$$

This procedure is repeated for every component individually, but this represents just one possible system damage response. To reflect the full distribution of possible responses, a technique such as Monte Carlo simulation or Latin hypercube sampling should be used to repeat the damage assignment for all components and generate multiple system damage responses. The system performance and loss calculations should be calculated for each system damage response.

For pipelines, whose damage is defined by a repair rate function, occurrences of the same typology exposed to the same ground motion are grouped together. The appropriate function for that typology is then used to calculate the average repair rate for that group. It is commonly assumed that the location of repairs follows a Poisson distribution (e.g., Hwang et al. 1998; Adachi and Ellingwood 2008). The Poisson distribution can be used to determine the probability that a specified number of repairs will occur on a particular section of pipe based on its length and repair rate. The expression for the Poisson distribution is shown in Eq. 4, where n is the number of repairs, RR is the repair rate, and l is the pipe length:

$$P[N = n] = e^{-RR \times l} \frac{(RR \times l)^n}{n!} \quad (4)$$

Adachi and Ellingwood (2008) proposed a simple method to determine pipeline failure. For a section of pipeline, Eq. 4 can be used to determine the probability of at least one repair. Then a random number is sampled from a uniformly distributed random variable between 0 and 1. If the random number is below this probability, then that section of pipeline is assumed to have failed. This is repeated for all sections of pipeline within a group and then for all groups to simulate a pipeline system response. To reflect the probability distribution, however, multiple pipeline system responses should be generated using a Monte Carlo simulation technique.

A more detailed analysis can be undertaken to determine how many repairs occur on each section of pipe, which is useful for evaluating flow reductions. In a Poisson process the probability distribution of the interval between events can be described exponentially. Therefore by repeated sampling from an exponentially distributed random variable with a rate parameter equal to the repair rate, it is possible to simulate the locations of repairs along a section of pipe (Hwang et al. 1998). The sampling continues until the sum of all the length intervals between repairs exceeds the length of pipe being assessed. Alternatively the number of repairs on each pipe section can also be evaluated directly by using Poisson distribution random number generation with the repair rate and pipe length as parameters. The repairs can be further classified as either a break or a leak by sampling from a uniformly distributed random variable between 0 and 1 and comparing this value to the corresponding probabilities for breaks and leaks, which are deduced empirically from historic data. Since the simulation of the number of repairs on each pipe section is just one possible network response, the simulation should be repeated multiple times.

Measuring System Performance Based on System Damage Response

There are two paradigms for measuring system performance: connectivity analysis and serviceability analysis. Connectivity analysis determines whether two points in the system remain connected and so can be used to determine whether a demand node (customer) remains connected to a source node. Serviceability analysis determines not just whether a customer is connected to a service but also what the quality of that service is.

To determine the connectivity between two points only requires knowledge of the damage or failure state of all the components between those points. If there is a path from a source node to a customer node in which all components are functional, then a connection exists. For large networks, however, it may not be feasible to

manually identify connections between all source-demand pairs, and computational techniques may be required. A simple metric of connectivity for infrastructure is to count the number of customers who are disconnected from an infrastructure system after an earthquake. However, since infrastructure systems can be modeled as networks of nodes and edges, it is possible to apply a field of mathematics known as graph theory to compute more complex metrics of connectivity that capture phenomena such as redundancy and path length (Duenas-Osorio et al. 2007), although these are not discussed further here.

For serviceability analysis, each infrastructure system will have its own unique metrics and methodologies for evaluating system performance in terms of service flow levels or quality. In general physical flow evaluations can be used to quantify the post-earthquake capacity of an infrastructure system. For the electric power system, for example, it is possible to determine flow at each node by solving a set of power flow equations simultaneously to find an equilibrium state across the network (Ang et al. 1996), while hydraulic analysis can be used for flow calculations in the potable and waste water systems. The methods for each individual infrastructure system are not described here but they are based on established physical models which can be found by consulting relevant texts.

A simple serviceability metric that can be applied to all infrastructure systems is to compare capacity or supply to customer demand as a simple ratio. Another type of metric is to determine whether an infrastructure system is able to provide service at some threshold condition, e.g., potable water at sufficient pressure and quality or electric power at sufficient voltage. Table 2 lists some examples of metrics that may be used to measure serviceability for different infrastructure systems, although this list is not exhaustive.

Irrespective of the system performance metric selected, it should be evaluated for all system damage responses that exist for each scenario earthquake. The final calculations for loss estimation should include appropriate statistical methods to make use of the full distribution of impacts that this generates.

Damage to Infrastructure: Modeling, Table 2 List of serviceability system performance metrics for infrastructure systems

Infrastructure system	Serviceability metrics
Electric power	Power supply/demand ratio, voltage reduction
Potable water	Water supply/demand ratio, hydraulic pressure reduction
Waste water	Capacity/demand ratio, probability of overflow
Natural gas	Gas supply/demand ratio
Fuel	Fuel supply/demand ratio
Telecommunications	Probability of call not being connected
Highways	Travel time delay, increase in travel distances

Restoration Functions

The purpose of restoration functions is to evaluate the time it might take for damaged infrastructure components to be repaired. This is important for determining indirect losses, which are affected by the outage time of infrastructure systems. A restoration function will provide information on the average repair time for a component based on its damage state or the average percentage of repairs that will take place within a specified time period (Cagnan et al. 2006). Such functions may be derived empirically or be based on assumptions for available resources and work rate. If derived empirically there will be some uncertainty associated with the function, and this should be accounted for in its application. Figure 4 shows a fabricated example of a component restoration function. By evaluating the repair times for components, it is possible to reevaluate system performance metrics at time steps after the earthquake based on improved system conditions. This in turn means that business interruption impacts and indirect losses can be better estimated.

Summary

This entry has summarized the importance of modeling earthquake-induced damage to infrastructure systems and the steps involved

including the uncertainties in the process. It has described the purpose of infrastructure system classification, the types of infrastructure components that exist, and the procedure for creating an inventory of infrastructures. It has explained the different uses of probabilistic fragility curves and deterministic repair rate functions to evaluate damage for infrastructure nodes and edges, respectively, as well as the differences between descriptions of physical damage and operational failure. Damage to infrastructure can be compared to both peak ground acceleration and peak ground velocity, with the former most relevant for above-ground components and the latter most appropriate for buried components. Although many infrastructure components are susceptible to damage caused by ground deformation, there are no established methods for predictive modeling of this risk. Although it is common to use probabilistic seismic hazard assessment to evaluate ground motions for building damage assessment, for infrastructure systems, because of their systemic and spatially distributed nature, it is more valuable to use realistic scenario earthquakes reinforced by simulation techniques to account for uncertainties in earthquake attributes if this is required. The systemic nature of infrastructure means that it is important to know which, and not just how many, components are damaged. Damage can be assigned to specific components by either grouping components together by typology or by considering each component individually, but in both cases uniform random assignment is used and so a simulation technique is required to account for uncertainties. For pipelines it is often assumed that the distribution of damage follows a Poisson distribution. Similar methods involving random assignment and simulation techniques are used to locate damages making use of exponentially distributed rather than uniformly distributed variables. Because of the uncertainties in damage assignment, there should be multiple damage state scenarios for each earthquake. System performance can be measured either in terms of connectivity between source nodes and consumers or as a measure of the level of service being provided. Connectivity analysis is more straightforward

Damage to Infrastructure:

Modeling, Fig. 4 An example of a restoration function to evaluate repair time of infrastructure components

D

since it only requires knowledge of the network topology and does not require physical models to be solved. However level of service analysis can generate a more informative view of the impacts of damage to the system. Finally restoration functions can be used to estimate the length of time it will take to repair the components. Since this method for modeling infrastructure damage uses simulation techniques for both earthquake hazard and damage state assignment, it will not produce a single outcome but rather a distribution of potential outcomes. Statistical measures and techniques therefore need to be applied to make inferences from this distribution.

Design of Cable-Supported Bridges: Control Strategies

Konstantinos Gkoumas, Francesco Petrini and Franco Bontempi

Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Rome, Italy

Synonyms

Cable-supported bridges; Cable-stayed bridge control; Performance-based design; Structural control; Suspension-bridge control

Introduction

The introduction of cable-supported bridges in modern-day bridge engineering, in the form of cable-stayed and suspension bridges, allowed to overcome spans unimagined decades ago. This was helped by advances in construction, materials, equipment, and numerical methods. Nowadays, the implementation of cable-supported structural schemes allows to span lengths in the range from 200 m to 2,000 m (and beyond), thus covering approximately 90 % of the present span range (Gimsing and Georgakis 2012).

Cable-supported bridges are basically divided into two types: cable-stayed and suspension bridges. Although both have as common factor the cable support, their geometry and structural configuration are radically different.

Cable-stayed bridges, in which the bridge deck is supported by straight cables directly by the pylons, emerged in their modern form initially in Europe after the Second World War. Since then, their span has been increased significantly. As of 2014 the bridge to Russky Island (Russia) is the world's longest cable-stayed bridge, with a 1,104 m long central span, followed closely by the Sutong Bridge (China) which spans 1,088 m, some four times the span of the 1958 Theodor Heuss Bridge over the Rhine, an epitome of the modern cable-stayed scheme.

Even though evolution in cable materials towards strength and weight is nowadays impressive, cable-stayed bridges are limited by the stiffness of their superstructure. Simply put, the weight of the bridge superstructure would create a sag in the cable, leading to nonlinear behavior. For this reason, for longer spans, the suspension scheme, in which the deck is supported by suspension cables on vertical hanger ropes, is preferred. The suspension bridge with the longest central span in the world is the Akashi Kaikyo Bridge in Japan, completed in 1998, with a central span of 1,991 m. The feasibility of longer spans has been demonstrated, with different design paradigms at a conceptual or preliminary stage.

Nowadays, cable-suspended bridges are designed in different schemes (e.g., self-anchored, multi-span), in different materials (essentially steel and concrete), and with different deck types (e.g., truss, plate). Several variations to the structural form have been successfully built as a variation of either forms (self-anchored suspension bridges, side-spar cable-stayed bridges, etc.) or as a combination (cable-stayed-suspension hybrid bridges).

In general, cable-supported bridges, due to the fact that they are supported by cables which constitute elastic supports, behave very well under earthquake excitation. Nevertheless, structural control for seismic loads is equally a concern for seismically active regions (with several cases in the USA, Japan, China, Turkey, and Greece). The issue is the structural behavior to long-period and long-duration ground motion. The principal seismic concern is the pounding between the deck and the abutments. This also accounts for the differential motion at the support system (towers), influenced also by the spatially varying soil conditions.

Performance Requirements and Design Issues

Both cable-stayed and suspension bridges have unique characteristics compared to ordinary structures and are characterized by a flexible

design, which mainly depends on the specific structural configuration, and by a low damping of the stay cables or hanger ropes. The flexible design may lead to unwanted motion or vibrations that could compromise the bridge safety and serviceability performance and even lead to immediate structural failure and also have an influence on the fatigue performance. Excitations due to wind, earthquake, or anthropic loads (railway, traffic, pedestrian loads, etc.) are the principal causes of unwanted vibrations.

Unlike conventional bridges, cable-suspended bridge design is not covered by bridge codes, standards, and specifications. Nowadays, performance-based design (PBD) is mainly employed for the seismic design of cable-suspended bridges (Bontempi 2006).

The dynamic wind action is the principal design concern (especially for longer spans), since it affects different parts of the bridge (deck, pylons, main cables, and hanger ropes of a suspension bridges; stay cables of a cable-stayed bridge). Thus, the principal concern is the alleviation of wind-induced vibration. The commonly observed aeroelastic phenomena (wake galloping, torsional and coupled flutter, and vortex-induced vibrations) have a strong influence on the bridge behavior and are usually suppressed or controlled by appropriate design measures and control strategies. Furthermore, bridge substructures and components have been shown to act as bluff bodies, resulting in self-excited vibration of the bridge.

Vibrations due to anthropic (pedestrian, railway, and traffic) loads can be of issue on a case-by-case basis, depending on the bridge type and use. Other additional effects can be an issue (e.g., the rain-induced vibration that mostly affects cables). Design solutions and countermeasures for these vibration effects have been applied, after meticulous studying during the years, starting from notable disasters and failures (e.g., the wind-induced collapse of the Tacoma Narrows Bridge in 1940 caused by aerodynamic flutter or the synchronous lateral excitation of the pedestrian London Millennium Footbridge in 2000). In the latter, frame-mounted viscous dampers and tuned mass

vibration absorbers were retrofitted after the initial undesirable performance of the bridge.

Regarding earthquake excitation, due to its (typically) very long fundamental periods, seismic behavior of cable-supported bridges is in general satisfactory and easily reparable with extraordinary repairs (replacement of fuse restrainers, etc.). Seismic loads have in general a direct influence on the foundations and towers, while the deck is indirectly influenced.

For seismic design, performance-based earthquake engineering (PBEE) design entitles bridge owners and stakeholders to decide on the behavior of the suspension bridge under different design solutions in terms of seismic vulnerability assessment. Usually, two seismic hazard levels are identified, with performance criteria related to safety or serviceability: the design earthquake and the maximum considered earthquake. These hazard levels are characterized by different probabilities of exceedance (or return periods) for the earthquake. All other hazards (e.g., high wind) are fulfilled also on the basis of appropriate limit states (e.g., ULS, Ultimate Limit States; SLS, Serviceability Limit States), while additional limit states (e.g., durability, fatigue, impact, etc.) are appropriately defined on the basis of the tender design document and the bridge site.

For long-span bridges, one of the principal design issues is the asynchronous earthquake excitation. While a normal structure frequently has a rather limited imprint, a long-span bridge is supported by towers placed sometimes hundreds of meters away. Thus, the seismic excitation from pylon to pylon can vary in time and intensity, and a uniform ground motion assumption is not realistic anymore.

Although the phenomenon is complex, the spatial variation of an earthquake mainly is divided for simplification in three effects and conditions: the geometric incoherence effect, the wave passage effect, and the local soil conditions. The asynchronous earthquake motion in bridges has shown to have an effect on the deck displacement during earthquake, which in cable-supported bridges is in part mitigated by the cables.

There are reports of ordinary bridge failures that may have been caused or aided by differential support motion during earthquakes (Burdette et al. 2008). However, it is difficult to fully attribute these failures to asynchronous earthquake motion, even though the phenomenon contributes to large longitudinal displacements between pylons. Nevertheless, different numerical analyses have shown that in long-span suspended bridges, the spatially varying ground motion may result in bigger structural response than the synchronous ground motion.

Structural Control

The mitigation of extensive vibration or motion has been a concern in the civil engineering field since the early conception of complex structural systems (high-rise buildings, long-span bridges), characterized by nonlinear behavior. The issue is to control how input energy (from strong wind, earthquake, etc.) is absorbed by a structure, by means of different methods and techniques, as an alternative to conventional design methods based on ductile response. Most commonly implemented methods include installing isolators or passive energy dissipation devices to dissipate vibration energy and reduce dynamic responses. In addition to these, with the advent of advanced computational methods (hardware and software), it is now possible to alter the structural configuration for mitigating the induced energy. In long-span bridge engineering, recent bridges mostly in Japan (e.g., the 1993 Rainbow Bridge in Tokyo) deploy such more advanced, “active” control strategies, especially for the transitory phase of construction.

Structural Control Strategies

In the civil engineering field, the term “structural control” with explicit reference to “active control” was introduced in 1972 by Yao (1972). Since then, the increase in the conception and design of complex structural systems and the increased demand for structural performance lead to numerous studies, design cases, and applications of structural control for such structures.

Design of Cable-Supported Bridges: Control Strategies, Fig. 1 Different control strategies (Adapted from Spencer and Soong 1999)

These were also motivated by devastating disasters through the years (earthquakes, tsunamis, typhoons, etc.) that put in evidence the issues of structural safety and reliability.

Structural control systems can be grouped into four broad categories (Housner et al. 1997):

- Passive control
- Active control
- Semi-active control
- Hybrid control

Figure 1 (adapted from Spencer and Soong 1999) provides an overview of the different control strategies, together with the no-control case (Fig. 1a).

Passive control is achieved by employing a passive energy device (PED), e.g., a Tuned Mass Damper or mechanical energy dissipation tool, that responds to the motion of the structure to dissipate energy or by isolating the structure from the ground and horizontal loads (base isolation systems). Passive control is employed exclusively by the motion of the structure, and no external force or energy is applied to effect the control (Fig. 1b). It is nowadays a broadly accepted vibration control strategy, with many consolidated cases worldwide, while in the recent years, innovative approaches have been applied in long-span bridge engineering. Typical applications of passive control in cable-supported bridges are in the form of dampers, placed principally

on the deck, pylons, and the hangers, and base isolation schemes on the foundations.

Active control, on the other hand, is a response-triggered control method. In other words, an external force is applied to the structure every time a displacement or vibration is measured by means of a control actuator. The latter takes input from sensors that measure the external excitation (open-loop control) and, in some cases, the structural response (closed-loop control) – (Fig. 1c). Although in the last three decades numerous methods have been proposed and many researches have been carried out, practical applications in cable-supported bridges are rather limited due to cost and reliability issues. Most of the applications regard pylon control during erection, as in the case of the Akashi Kaikyo Bridge. In fact, a change in the pylon height leads to a change in its natural frequency, something that poses as a challenge to deal with using a small number of mass dampers.

In between, two other methods have been widely studied (and applied in a few cases worldwide) that try to combine advantages and exclude shortcomings of the abovementioned control strategies.

In **semi-active control**, the control actuator does not directly apply force to the structure (as in the case of active control), but instead it is used to control the properties of a passive energy (Fig. 1d). Within the class of semi-active control, the use of controllable electrorheological (ER) and magnetorheological (MR) fluids in dampers has found ground in the recent years, with applications mostly on the stay cables of cable-stayed bridges.

Finally, **hybrid control** consists in the combined application of both passive and active methods. This means that a part of the control derives from a passive control device, something that alleviates the required effort in terms of forces and energy for the active device (Fig. 1e). Hybrid control is applied as an alternative to active control during the erection of towers of suspension bridges. Spencer and Nagarajaiah (2003) report several cases of hybrid control in bridges during tower erection.

Compared to pure active control, semi-active and hybrid control strategies have the advantage

that the passive control part can function also during a power failure, thus providing a minimum degree of protection.

Considering the above, there are significant advantages and disadvantages for each control method. Also, optimal fields of application can be significantly different: in general, consolidated passive methods are preferred for their cost-effective solution and reliability. However, in the last years, alternative active, semi-active, or hybrid methods are implemented in case a passive method results inadequate (two cases worth mentioning are the implementation of active methods as a support to passive ones during the tower erection and the use of semi-active tendon control). Finally, different control methods and devices are preferred for different parts of the structure.

Structural Control Issues

Taking into account what was said above, the following sections overview control devices and strategies with respect to different parts of cable-supported bridges. On the basis of consolidated cases, Fig. 2 synthesizes the control options.

It should be noted that many of the issues can be dealt with an improved design or structural modifications. This is the case, for example, for flutter- and vortex-induced vibration suppressions on bridge deck, obtained by means of section modifications or aerodynamic countermeasures (e.g., deflectors, fairings, and flaps). Similarly, an appropriate designed cable cross section and surface can minimize cable vibration.

Foundation Isolation

Foundations transmit lateral loads to the entire bridge through the connection to the other parts (principally deck and cables). The typical control strategy in long-span bridge design is base isolation. Base isolation, that is, to decouple the bridge superstructure from its foundations, is now considered a mature technology. A modern interpretation of this strategy has been applied in the recent years in several long-span suspension and cable-stayed bridges.

Two notable cases are the 2004 Rio-Antirrio multi-span cable-stayed bridge in Greece and the

Design of Cable-Supported Bridges: Control Strategies, Fig. 2 Control strategies for different substructures of cable-supported bridges

currently under construction Izmit Bay Suspension Bridge in Turkey. Although both bridges are entirely different for conception and structural scheme, a similar base isolation system is applied to the tower foundations of both of them.

The Rio-Antirrio cable-stayed bridge spans approximately 2.9 km, including the approach viaducts, with the three central spans being 560 m long and the adjacent spans 286 m, all supported by four towers. The bridge is designed to withstand earthquakes with a P.G.A. of 0.48 g and tectonic movements up to 2 m between consecutive pylons (Jacques 2011). It is positioned in a highly seismic area, less than 10 km from the Psathopyrgos fault and the Rion-Patras transfer fault.

The Izmit Bay Suspension bridge has a 1,550 m long main span and two 566 m side spans. It is supported by towers placed in 40 m water depth, with a top elevation of 252 m above the sea level.

Both bridges were designed for severe environmental conditions, in deep water depth and for strong winds, and are positioned in highly seismic areas, with nearby active faults. Their base isolation system at the foundation level constitutes an emblematic example of the base isolation concept in modern long-span bridge designs.

The tower foundations (Fig. 3 shows the scheme of the Rio-Antirrio Bridge tower foundations) are placed on a gravel bed on soil reinforced with tubular steel pile inclusions not connected to the foundations. The gravel layer behaves as a plastic hinge (with inelastic deformation and energy dissipation taking place),

Design of Cable-Supported Bridges: Control Strategies, Fig. 3 Overview of the Rio-Antirrio Bridge foundation (From Jacques 2011)

while the ground reinforcement provides an overstrength which prevents the development of rotational failure modes of the foundation. In short, this solution allows for rocking, gapping, and sliding of the foundation. Should the seismic force exceed the design one, the failure mode would be pure sliding and not rotational, easily accommodated by the bridge.

Pylon Control

Pylons are connected to the bridge foundations and thus are affected by ground motion. However, due to their high vibration modes, they are prone mostly to wind-induced vibrations. Consolidated practices implemented are based on passive control, using different systems.

Design of Cable-Supported Bridges: Control Strategies, Fig. 4 TMDs on the Akashi Kaikyo towers (Courtesy of “Honshu-Shikoku Bridge Expressway Co., Ltd.”)

TLDs (Tuned Liquid Damper systems) dissipate energy using a secondary mass in the form of a body of liquid introduced into the structural system and tuned in such a way to act as a dynamic vibration absorber. TLDs are particularly effective for the suppression of lateral vibrations (e.g., due to wind or pedestrian loads) and were used for vibration control of the Toda Park Bridge in Japan. Similar devices to TLDs are TSDs (Tuned Sloshing Dampers) and TLCDs (Tuned Liquid Column Dampers).

Another important issue is the control of the pylons during erection and also during the cable spinning, since their frequency varies significantly in that phase. The use of passive dampers (mostly Tuned Liquid Dampers) proves to be ineffective since they have to be constantly tuned to the new pylon configuration. In the past 20 years, this problem has been dealt with the implementation of active and hybrid control strategies. This is a particularly consolidated practice in Japan, with several cases reported

(Fujino and Siringoringo 2013). The first application of active mass dampers (AMD) to a bridge pylon was on the 1991 Rainbow suspension bridge in Tokyo, Japan. The AMDs were placed on top of the outer edge of the 126 m high pylons to help reduce large-amplitude vortex-induced vibration. During erection, the Akashi Kaikyo Bridge pylons were equipped with two sets of Hybrid Mass Dampers (HMD), a combination of a combination of passive TMD and active control actuator. Figure 4 (Courtesy of “Honshu-Shikoku Bridge Expressway Co., Ltd.”) outlines the position of the vibration control devices on the bridge tower.

Deck Control

As in the case of the pylons, the deck of a long-span bridge is exposed to turbulent wind and thus to different wind-induced phenomena. Depending on the bridge configuration, the bridge deck is subjected from minor to average solicitation from earthquakes. The former is

particularly truth for bridges with a deck totally suspended (without deck-pylon connections). Vibrations and displacements due to anthropic loads (railway, highway, and pedestrian) have to be controlled as well.

An important issue is the pounding effect that usually takes place during strong earthquakes between the main span and the approaching span of long suspended bridges or the main span and the pylon of self-anchored suspended bridges and may cause considerable damage of the colliding bridge deck segments, in correspondence to the position of the expansion joints. This is important considering that the vibration periods of the flexible and usually unrestricted main span are different from the vibration period of the pylon or the approaching spans.

For long spans the usual design practice nowadays for seismic isolation is to have a fully or semi-floating deck (where the deck is suspended from stay cables or hanger ropes and there is little or no contact at the pylons through lateral control devices and bearings).

Control devices are placed usually between the deck and the pylons and the main span and the approaching span, and consolidated practice indicates the implementation of passive devices. Again, design decisions drive the adoption of control devices. In fact, a compromise has to be made for what regards the longitudinal movement and the possible deck-pylon connection, considering both impact forces (earthquake, wind, vehicle braking) and slow developed stresses due to the temperature gradient. The compromise lies in choosing between a fully floating system, prone to an elevated movement, and a fixed deck-pylon that results to a more rigid system. For very long spans either case is impossible, and in many cases, an intermediate solution is adopted, with the deck-pylon being connected with damping systems that provide limitations to the free movement of the deck.

Shock Transmission Units and (usually fluid) dampers are implemented to limit longitudinal deck movements, of the otherwise undamped deck, and, in the case of suspension bridges, to avoid pounding between the stiffening trusses and the towers.

Shock Transmission Units (STUs), otherwise known as Lock-Up Devices (LUDs), are devices that allow the slow movement of the deck when the bridge structure slowly expands and contracts (under thermal loads or creep) but lock-up (under seismic or wind). In this way, the structural system responds differently to slowly applied loads (daily temperature variation and creep) and fast loads (impact, earthquake, wind gusts). Thus, large seismic or extreme event forces are restricted from the bridge towers.

STUs have been used broadly in major cable-supported bridges. Patel (2013) reports several applications both in suspension bridges (the Storebaelt in Denmark) and cable-stayed bridges (the Sidney Lanier in the USA, the Second Severn Bridge in the UK, the Seohae Grand Bridge in South Korea, and the Stonecutters Bridge in Hong Kong). In many cases, the concern was not only seismic but wind loads as well (Fig. 5).

Fluid viscous dampers (FVDs) are passive control devices that dissipate energy by applying a resisting force over a finite displacement. The damper's output force acts in a direction opposite to that of the input motion. Such dampers consist usually of a hollow cylinder filled with a fluid (typically silicon based). As the damper piston rod and piston head are stroked, fluid is forced to flow through orifices either around or through the piston head, something that produces a force in the opposite direction. The friction between fluid particles and the piston head leads to energy dissipation in the form of heat. Fluid viscous dampers can be tuned to have either linear or nonlinear behavior, depending on the specific application. A strongly nonlinear behavior means that the opposing force is very low for low applied forces but can be high as the applied loads increase.

FVDs have been implemented in many long-span suspended bridges in the last years, especially in China. An example is the Xihoumen Bridge with a main span of 1,650 m (currently the second longest suspension bridge in the world) that relies on four stroke dampers that have a range of movement of $\pm 1,100$ mm installed at the end of the bridge deck.

Design of Cable-Supported Bridges: Control Strategies, Fig. 5 STU units under installation in the Stonecutters Bridge (From Patel 2013)

Other innovative ideas include the case of the Sutong Bridge, the world's second longest cable-stayed bridge with a span of 1,088 m and a totally suspended deck; eight isolators are used to reduce the axial motion of the suspended deck (Fig. 6). Each isolator consists in a combined spring-damper element (consisting in a fluid damper, an elastomer spring, and an internally placed gapping mechanism). For the initial 85 % of the available displacement from the neutral position, the isolator has only damping response (that accommodates also the daily thermal expansion and contraction of the suspended deck) and for the rest 15 %, combined spring and damping response. This, since the long period of the deck, provides intrinsic vibration control in the longitudinal direction, while additional displacement has to be limited in the longitudinal direction for other events (e.g., vehicle braking forces, typhoon loads). The control device has a maximum displacement of 85 cm of which about 10 cm is the final combined spring and damping.

Lateral movement is also an issue, especially for floating deck configuration. For example, in the Rio-Antirrio cable-stayed bridge, the

continuous deck is free to accommodate the movements from seismic excitation in the longitudinal direction, since it is fully suspended. The movements in the transverse direction are controlled by nonlinear fluid viscous dampers and fuse restraints installed parallel to the dampers (Fig. 7). In this way, the deck is linked rigidly to the substructure when subjected to lateral loads not exceeding the design capacity. In major seismic events, the fuse restrainers are designed to fail and leave the dampers free to dissipate the earthquake-induced energy acting upon the structure. After their failure the deck is free to swing coupled to the dampers.

Other passive control devices (solid viscoelastic dampers, metallic dampers, friction dampers, etc.) have a different hysteric behavior with several advantages and disadvantages also for what concerns their reliability.

In the case of the Tianxingzhou Yangtze River Bridge in China (a bridge with a main span of 504 m, the longest combined road and rail cable-stayed span in the world), a combination of magnetorheological (MR) and hydraulic dampers is used in correspondence to the piers, to limit

Design of Cable-Supported Bridges: Control Strategies, Fig. 6 Sutong Bridge pylon-deck viscous damper system (above) and device schematic (below) (From You et al. 2008)

deck vibrations. MR dampers consist of a hydraulic cylinder containing a solution that, as their name suggests, can reversibly change, when exposed to a magnetic field or electric current, from a free-flowing liquid to a semisolid with controllable yield strength. These devices allow to actively control impact forces (due to train braking and earthquakes), where the hydraulic damper provides a velocity-related recovery (damping) force that relieves slow movements (e.g., due to daily temperature change).

Cable Control

Stay cables and hanger ropes are characterized by very low internal damping, relatively small mass, large flexibility, and considerable length. They are susceptible to vibrations due to direct loading (caused by wind, rain, and other extreme events

such as snowstorms) or, indirectly, due to the vibrations of the supported deck. To suppress these vibrations, commonly passive devices are used (hydraulic, oil, rubber, or viscous dampers). Usually these devices are attached to the cables near the deck anchorage, although other configurations are possible.

More recently, adaptive dampers have been implemented on many occasions. Their principal advantages compared to passive dampers lie in the easy tuning (by adjusting the current or voltage) both before and after the installation and for different modes of vibration.

Duan et al. (2006) report the first successful application of MR dampers for the retrofitting of the Dongting Lake Bridge in China. A total of 312 dampers were installed on 156 cables of the bridge (two for each cable), at a height of 1.8 m

Design of Cable-Supported Bridges: Control Strategies,

Design of Cable-Supported Bridges: Control Strategies, Fig. 8 Cable-stayed vibration control with MR dampers at the Dongting Lake Bridge (left, from Duan

et al. 2006) and the Shandong Binzhou Yellow River Bridge (right, from Li et al. 2007)

from the bridge deck, and in an inclined T-shape support configuration (Fig. 7). A similar approach has been used in the retrofitting of the Shandong Binzhou Yellow River Highway Bridge (a three-tower cable-stayed bridge in China, with two main spans of 300 m). The bridge suffered unaccepted vibrations after its opening in 2004 and was retrofited with MR dampers on 20 of its longest stay cables (Li et al. 2007; Fig. 8).

Other recent applications of MR dampers for cable control include the Jiashao Bridge in China, the world's longest and widest multi-span cable-stayed bridge, and the Sutong Bridge.

Overview of Control Methods

The above are reassumed in Table 1. Many issues can be minimized by adopting an appropriate structural shape. For example, deck

Design of Cable-Supported Bridges: Control Strategies, Table 1 Overview of principal control issues and methods for cable-suspended bridges

Substructure	Principal issue(s)	Control type	Control device
Foundations	Earthquake	Passive (seismic isolation)	Foundation design
Towers	Vortex-induced vibrations	Passive	TMD (Tuned Mass Dampers)
	Earthquake	Active	TLD (Tuned Liquid Dampers)
		Semi-active	TSD (Tuned Sloshing Dampers)
		Hybrid	TLCD (Tuned Liquid Column Dampers) HMD (Hybrid Mass Dampers)
Stay cables and hanger ropes	Wind	Passive	Viscous dampers
	Rain	Active	MR (magnetorheological) dampers
	Ice		
Deck	Vortex-induced vibrations	Passive	FVD (fluid viscous dampers)
	Earthquake	Semi-active	STU (Shock Transmission Units)

	Vehicle		TLD
	Train		

vortex-induced vibration can be suppressed by changing the section or by using aerodynamic appendages or flaps.

Seismic Response of Cable-Suspended Bridges

In the last 30 years, many new bridges were constructed, and many old bridges were retrofitted with instrumentation systems. Measurements from these systems during major seismic events are allowed to assess the seismic performance of the structures, the performance of the control systems, and the post-earthquake behavior of the bridge. A number of significant case studies based on SHM (Structural Health Monitoring) data or field investigations are reported below.

Akashi Kaikyo Bridge

The Akashi Kaikyo Bridge, presently the suspension bridge with the longest span in the world, was hit by the Hanshin Kobe earthquake while under construction. The epicenter of the 6.8 magnitude earthquake was located just about 2–3 km

east of the bridge. The construction of the foundations, both towers, and main cables had been completed before the earthquake occurred, but neither hangers nor girders had been attached to the main cables, while the stiffening girders were not yet in place. The bridge towers were equipped with temporary semi-active mass dampers, tuned for wind excitation.

There was no damage to bridge structures, but displacements of the four foundations were caused by crustal movements. There was also an 80 cm elongation at the center span and 30 cm at one of the side spans. There was also a change of angle horizontally and vertically at the towers and at the anchorages. The construction reprised accounting the above facts in the updated design (Kitagawa 2004).

Higashi-Kobe Bridge

The Higashi-Kobe Bridge is a cable-stayed bridge with a center span of 485 m. With the aim of augmenting the fundamental period of bridge, the bridge deck is supported by towers and piers in such a way that the girder is movable in the longitudinal direction independently from the towers; thus, the displacements are mainly

restricted by the cables. The bridge is equipped with two vane-type oil dampers at the end piers, and the cables are arranged in a harp pattern, in order to prevent an excessive longitudinal displacement. The vane-type dampers help in preventing excessive displacement since its effect increases with the velocity of the girder movement. During the 1995 Hanshin Kobe earthquake, the bridge suffered significant yet repairable damage (Naganuma et al. 2000). The upper set of bolts of the transverse wind brace on the end pier broke, and the upper shoe was taken off, something that put excessive force on the vane-type dampers that were not designed to carry transversal loads. It should be observed that the design acceleration was significantly lower than the one monitored during the event.

Yokohama Bay Bridge

The Yokohama Bay Bridge with a total length of 860 m and a central span of 460 m is a densely instrumented cable-stayed double deck highway bridge in Japan. The bridge opened in 1989 and was already retrofitted in 2005 for additional seismic safety. Specifically, to accommodate longitudinal girder displacement in case of large earthquake, LBCs (link-bearing connections) were implemented: 10 m long end-links at the two end piers and 2 m long tower links at the two towers. The bridge is located 180 km from the closest fault area of the 2011 9.0 magnitude Great East Japan (Tohoku) Earthquake, notably the largest earthquake in Japan's modern history. The bridge experienced large transverse displacements during the earthquake (55 and 62 cm in the top of the tower and the mid-span, respectively) and very small longitudinal displacements (15 cm). No damage was detected. The excessive transversal and longitudinal motion leads to scratch marks on the wind shoes and a few crushed nuts and bolts on one of the tower links (Siringoringo et al. 2013).

Rio-Antirrio Bridge

The Rio-Antirrio Bridge is a multi-pylon cable-stayed bridge designed to withstand seismic

events by means of different mechanisms between the pylon and the soil and the deck and the pylons and abutments (where a dissipation system with hydraulic dampers is installed). The seismic design was tested during the 2008 6.5 magnitude earthquake about 35 km from the bridge location, which had no permanent effects to the bridge. The bridge suffered very mild damage, principally in the lateral restrainers (sacrificial elements) that yielded (Papanikolas et al. 2010). As a remedial, the deck was realigned and six fuses were replaced.

Ji-Lu Bridge

The Ji-Lu Bridge is a single pylon cable-stayed bridge with prestressed concrete girders that suffered important damage in September 1999 during the 7.7 magnitude Chi-Chi, Taiwan earthquake (Kosa and Tasaki 2003). The 120 + 120 m bridge, supported by a single concrete pylon, was under construction at the time. The damage was widespread, extending over the main girder, the main pylon, and the two piers, due to the seismic force that acted in both the axial and the perpendicular directions of the bridge. Pounding occurred between the main span and the approaching spans and between the superstructure and the towers. Also, one cable was put out from the anchorage section of the pylon, and many sockets were also pulled out from the anchorage section.

Shipshaw Bridge

The Shipshaw Bridge is an asymmetrical single pylon cable-stayed bridge in Quebec, Canada, with a deck 183 m long supported by a double-leg steel tower. At a later inspection after the 1988 Saguenay 6.0 magnitude earthquake (Filiatrault et al. 1993), it was found that one of the four interior anchorage plates in one abutment failed. Although the damage cannot be linked directly to the earthquake, later analysis point towards this, together with the fact that the anchorage plates were already subjected to high stress concentrations. The bridge was immediately closed, and all four plates in correspondence to that abutment were replaced (Table 2).

Design of Cable-Supported Bridges: Control Strategies, Table 2 Notable earthquake events and bridge behavior

Bridge	Type	Length (m) (total/longest span)	Seismic event	Magnitude (Mw)	Damage	References

Future Trends

Future trends of cable-suspended bridge vibration control will run alongside other developments for smart bridges and SHM. SHM was in fact pioneered in long-span cable-suspended bridges in Japan, China, and Korea parallel to active or semi-active control methods. A bigger integration of control methods with SHM systems and instrumentation is expected parallel to current developments of bridge SHM in major areas around the world (Korea, Koh et al. 2009; Hong Kong, Ni and Wong 2012; Japan, Fujino and Siringorino 2008; and China, Sun et al. 2009).

Another aspect is the integration of Energy Harvesting (EH) methods with vibration suppression and control devices, for supplying power to autonomous sensors for SHM applications or for self-powered damper systems. Applications are expected using electromagnetic dampers (Shen and Zhu 2014) and piezoelectric or other materials once issues related to fatigue and real-life stresses are resolved.

The implementation of active, semi-active, and hybrid control strategies is expected to increase, even though passive vibration

suppression methods could benefit from innovative research (e.g., using passive nonlinear energy sinks – Wierschem et al. 2011).

Summary

Vibration control is a major topic for cable-supported bridges. Even though this structural configuration is less sensitive to earthquake-induced vibrations, issues related mostly to pounding have to be accounted for in the design and retrofitting stage. In the last years there are consolidated cases of active or semi-active control in major bridges around the world, with significant performance gains compared to classic passive methods. This trend is expected to increase with the increase of reliability of such methods.

Dynamic finite difference method; Dynamic finite element method; Earthquakes; Geosynthetics; Metallic reinforcement; Pseudostatic; Reinforced soil; Retaining walls; Seismic design; Sliding block

Introduction

Mechanically stabilized walls (MSWs) are a class of earth retaining walls that use horizontal layers of metallic or geosynthetic reinforcement placed within the wall backfill to create a composite mass of soil, reinforcement layers, and facing. This mass (or block) acts as a gravity structure to resist the destabilizing earth forces that act at the back of the reinforced soil zone. Details of some MSW types are illustrated in Fig. 1. The function of the gravity structure (reinforced zone including the facing) can be imagined equivalent to conventional gravity retaining wall structures including reinforced concrete T-sections. The advantage of MSWs over conventional gravity wall structures, based on North American experience, is that they can be constructed for as little as 50 % of the cost of traditional solutions.

History

The modern history of MSW structures can be traced back to the 1960s with the advent of steel strip walls first constructed in France. In the 1970s, modern polymeric sheet materials (geotextiles) were first employed as the soil reinforcement material in wall structures located in Europe and North America. Today, MSWs are ubiquitous for the earth retaining wall function. Their use and the methodologies to design these structures are well established and accepted. Conventional static design methods for structures in non-seismic areas have been extended to accommodate the additional loads that develop as a result of earthquake.

Reinforcement

The soil reinforcement materials that are used in MSWs can be broadly classified into metallic and geosynthetic categories. Metallic reinforcement includes steel strips, steel bar mats and ladders, welded wire, and steel anchor plates attached to the facing using steel rods. Almost all steel reinforcement products are galvanized for corrosion

protection. Geosynthetic reinforcement materials are high-performance polymeric materials whose primary constituent is typically polypropylene (PP), high-density polyethylene (HDPE), or polyester (PET). Geosynthetic reinforcement products are classified as geotextiles, geogrids, and strips. Woven geotextiles are sheetlike materials that have the appearance of a textile. Some geogrids are manufactured from punched and drawn polymeric sheets to create an open integral grid-like structure with square, rectangular, or triangular openings. Other geogrid products are manufactured from bundled polyester filaments that are knitted or woven together in longitudinal and transverse directions to form the geogrid structure. Geogrid strips are typically belts of aligned polyester filaments. The polyester core is protected by a polymeric sheath. Most often, geogrids are used in geosynthetic MSW structures because the geogrid apertures can better engage the backfill soil to transfer load from the soil to the reinforcement, particularly if the soil is a cohesionless sand or gravel.

Backfill Soil

Cohesionless soils such as sands and gravel are the preferred material for MSWs compared to fine-grained soils because they are easier to place and compact, are better draining, and have higher shear strength and stiffness. In fact, most government design guidelines in North America restrict the soil in the reinforced soil zone to these “select” materials. Limitations on soil type also apply for steel-reinforced MSWs in order to minimize corrosion of the steel.

Facing

MSWs must include a facing that acts as a construction aid to assist with placement and compaction of the soil at the wall face and ensures that the wall face will be stable at a vertical or near-vertical orientation over its design life. The simplest facing can be constructed by simply extending the primary reinforcement layers in a

capacity. (d) Pullout. (e) Tensile over-stress. (f) Internal sliding. (g) Connection failure. (h) Column shear failure. (i) Toppling

wrapped configuration at the wall face and tucking the free end of the wrap back into the reinforced soil mass. A temporary moving formwork is required to support each wrap during construction. These facings are flexible and cost-effective and best used for temporary structures when long-term durability of the facing is not a concern. More robust facings can be formed using welded wire cages, masonry or wet-cast concrete blocks, incremental concrete panels, or full-height concrete panels. Historically, steel soil reinforcement materials have been used in conjunction with incremental concrete panels that come in square or hexagonal shapes.

Design Concepts

Static Load Environments

MSWs are first designed to have adequate margins of safety against collapse and excessive deformation under static loading conditions.

Potential failure mechanisms are illustrated in Fig. 2 for the case of geosynthetic and metallic reinforced soil walls constructed with a modular block facing. External failure modes are related to the stability of the composite reinforced soil zone comprised of the backfill soil, reinforcement layers, and facing. The composite acts as a gravity block to resist sliding at the base of the block and overturning at the toe in response to active earth forces from the retained soil located immediately behind the block (reinforced soil zone). In addition, the block must not generate a bearing capacity failure in the foundation soil or excessive settlement. For walls with simple geometry, sliding resistance typically controls the length of the block in the direction perpendicular to the running length of the wall face and consequently the length of the reinforcement. Regardless of the computed minimum reinforcement length, design codes typically restrict the minimum length of the reinforcement to be not less than 60–70 % of the height of the wall.

Additional stability calculations for global stability must always be carried out, as is the case for any retaining wall structure, to ensure that the structure is not part of a larger failure mechanism that extends beyond the reinforced soil zone and into the foundation. These calculations can be carried out using conventional slope stability programs.

In order for the reinforced zone to maintain its coherence, it is necessary to design the reinforcement layers against internal stability modes of failure. These include tensile overstressing of the reinforcement leading to excessive deformation or even rupture and pullout of the reinforcement layers from the anchorage zone which extends from the location of the potential internal failure wedge to the free end of the reinforcement layers. In some cases it may be possible for a failure mechanism to propagate at an angle from the heel of the wall facing or at a higher elevation at the back of the facing column through the reinforced soil zone and into the retained soil zone. These failure mechanisms are called composite failures and are best investigated using circular or noncircular slope analysis methods implemented in slope stability computer programs that have been modified to include the tensile capacity of any intersected reinforcement layer. For reinforced soil walls with incremental panel or full-height panels, the internal sliding failure through the concrete facing is unlikely (Fig. 2f).

The design tensile strength of the reinforcement will vary depending on the reinforcement type. For steel reinforcement the unfactored tensile strength of the reinforcement is easily computed as the product of yield strength of the tensile member and the cross-sectional area. Most steel reinforcement products are galvanized for cathodic protection, and a sacrificial thickness of steel is included in the calculation of tensile load capacity to account for possible corrosion. This thickness is computed based on the soil type, porewater chemistry and resistivity, and design life. For geosynthetic MSWs, the reference tensile strength of the reinforcement from standard laboratory testing must be reduced to account for possible installation

damage, chemical degradation, and creep. Modern geosynthetic reinforcement products have been specially formulated to minimize degradation. Polyester geogrids and strips are manufactured with a coating for additional stability and for protection during installation and exposure to UV light.

The facing must also be stable over the life of the structure, and the connections between the facing and the reinforcement layers must have sufficient tensile capacity. Adequate connection capacity is most important for walls with a hard facing (e.g., concrete blocks and panels). For modular block walls, stability against toppling of the units at the top of the facing column and interface shear must also be ensured. The failure modes for column shear and toppling in Fig. 2h, i are unique to modular block walls and thus do not apply to incremental concrete panel, full-height concrete panel, and wrapped face walls.

Post-construction wall deformations for well-constructed MSWs should be less than 1.5 % of the wall height. Deformations for the same walls but using much stiffer steel reinforcement will be less. This difference may be a factor when deciding which category of reinforcement to use in a particular project.

Seismic Design

The potential modes of failure identified for static design of MSWs are equally applicable to the same structures subjected to additional loads due to earthquake.

Current methods for the earthquake design of MSWs fall into three categories: (1) pseudo-static methods, (2) sliding block displacement methods, and (3) dynamic finite element or finite difference methods.

Pseudo-Static Methods

The calculations for earthquake loads used in internal and external stability design of MSWs have historically been based on extensions of the classical (static) Coulomb wedge approach for active earth forces acting against retaining walls. The advantage of the method is that in the limit of no earthquake-induced ground accelerations, the equations for active earth force

Design of Mechanically Stabilized Walls (MSWs), Fig. 3 Active wedge geometry and interpretation of total active earth force P_{AE} due to wedge self-weight W and peak ground acceleration coefficients k_h and k_v

(or active earth pressure) are the same as for the static case. The disadvantages of the approach are that it is limited to simple wall geometry and ground conditions, and analytical solutions are limited to peak ground accelerations often not more than 0.3 g. Where analytical solutions are possible, the computed total earth forces are often very high resulting in excessively conservative design with respect to number of reinforcement layers, strength of the reinforcement, and length. Nevertheless, the general Coulomb approach is familiar to geotechnical engineers, and this makes it an attractive method.

The total active earth force (P_{AE}) acting against the back of the reinforced soil zone for external stability wall calculations and the back of the wall facing for internal stability calculations can be equated to the wedge with weight (W) shown in Fig. 3. For the simple geometry shown in this figure, the total active earth force (P_{AE}) acting against an inclined surface can be computed analytically as:

$$P_{AE} = \frac{1}{2}(1 \pm k_v)K_{AE}\gamma H^2 \quad (1)$$

Here, γ = unit weight of the soil and H = height of the wall. The total earth pressure coefficient (K_{AE}) is calculated using the Mononobe-Okabe equation which is an extension of the Coulomb equation:

$$K_{AE} = \frac{\cos^2(\phi + \omega - \theta) / \cos \theta \cos^2 \omega \cos(\delta - \omega + \theta)}{\left[1 + \sqrt{\frac{\sin(\phi + \delta) \sin(\phi - \beta - \theta)}{\cos(\delta - \omega + \theta) \cos(\omega + \beta)}} \right]^2} \quad (2)$$

Here, ϕ = peak soil friction angle, ω = wall/slope face inclination taken as positive in a clockwise direction from the vertical, δ = interface friction angle at the back of the wall (or back of the reinforced soil zone), β = backslope angle taken from horizontal, and θ = seismic inertia angle given by:

$$\theta = \tan^{-1} \left(\frac{k_h}{1 \pm k_v} \right) \quad (3)$$

Quantities k_h and k_v are peak horizontal and vertical seismic coefficients, respectively, expressed as fractions of the gravitational constant, g . The peak ground acceleration components are selected based on a site- or region-specific design accelerogram at bedrock, the distance from the earthquake, and the ground conditions above bedrock. The values of k_h and k_v are assumed to be constant at the back and through the entire reinforced soil mass.

There are different strategies to separate the static component of load on the back of the reinforced soil zone and the static load component on the reinforcement layers from the corresponding additional dynamic load components due to earthquake. For example, the additional horizontal component of dynamic load (ΔP_{dyn}) against the wall face or back of the reinforced soil zone can be expressed as the difference between the total earth force (P_{AE}) and static earth force component (P_A) as follows:

$$\Delta P_{dyn} = P_{AE} - P_A \quad (4)$$

Equivalently,

$$\Delta K_{dyn} = (1 \pm k_v) K_{AE} - K_A \quad (5)$$

Here, K_A = static active earth pressure coefficient and ΔK_{dyn} = incremental dynamic active earth pressure coefficient. In stability calculations the

Design of Mechanically Stabilized Walls (MSWs),

Fig. 4 External stability geometry and forces

forces or coefficients of earth pressure shown above must be multiplied by $\cos(\delta - \omega)$ when factor of safety expressions are for loads and resistances acting in the horizontal direction. As distance from the earthquake epicenter increases, the most important ground acceleration is the horizontal component, and the vertical component is typically ignored (i.e., $k_v = 0$). Furthermore, the likelihood of peak horizontal and vertical acceleration components of an earthquake arriving simultaneously is small. In practice, the choice of k_h is typically based on local experience or prescribed by design codes that are applicable to the site area. In current US practice, the location of the dynamic earth force component is assumed to act at the same elevation as the static component (AASHTO 2012). If the consequences of failure are high, then the same code recommends locating the resultant at a higher elevation.

The calculation of factor of safety against external base sliding is carried out by substituting P_{AE} for P_A in a conventional block sliding analysis and adding horizontal inertial forces due to the mass of the reinforced zone (sliding block) as illustrated in Fig. 4. Quantities W_s and W_w are the weight of the reinforced soil and the facing column, respectively. Typically, the horizontal inertial force due to W_s is reduced by setting $\lambda = 0.5$. The contribution of the facing column to horizontal inertial loads is usually applied to facings constructed with modular blocks and is ignored for thinner incremental or full-height concrete

panel wall systems. Quantity R in Fig. 4 is the sliding resistance at the base of the reinforced soil zone.

During an earthquake, additional dynamic transient tensile loads will be carried by the reinforcement. In the simplest approaches to internal stability seismic design, the dynamic load (T_{dyn}) due to earthquake is most often added to the static load (T_{sta}) calculated for the same structure as illustrated in Fig. 5. For example, the tensile reinforcement load T_{max} in a layer can be calculated as:

$$T_{max} = T_{sta} + T_{dyn} = K_r \sigma_v S_v + \Delta K_{dyn} \bar{\sigma}_v S_v \quad (6)$$

Tensile load is expressed with units of force per unit running length of wall. Here S_v is the reinforcement spacing and σ_v is the vertical stress acting at the elevation of the reinforcement due to soil self-weight and any uniformly distributed surcharge. The quantity $\bar{\sigma}_v$ is the average vertical stress over the height of the wall. For modular block wall systems, the horizontal inertial force due to the facing units over the layer spacing height S_v should be included in the calculation of T_{max} . The example here is simplified by conservatively ignoring wall-soil friction, wall inclination, and weight of the facing. Parameter K_r is the static earth pressure coefficient. For geosynthetic reinforcement, $K_r = K_A$. For steel reinforcement cases, $K_r \geq 1.2 K_A$ at the top of the wall (with actual values depending on steel reinforcement type) and decreases linearly with depth

Design of Mechanically Stabilized Walls (MSWs),

Fig. 5 Calculation of maximum internal reinforcement loads

D

to $1.2K_A$ at a depth of 6 m. The distribution of dynamic horizontal pressure in the above example is assumed to be constant over the height of the wall. However, assumptions regarding the distribution of this dynamic pressure component can vary based on reinforcement type (geosynthetic or steel) and between different design codes. As noted in the previous section on static design principles, the tensile load T_{max} in the reinforcement must not exceed a critical value to prevent overstressing that can lead to rupture. For static design of geosynthetic MSWs, this value is largely determined by the constant load creep behavior of these polymeric materials. However, under transient dynamic loading, the residual strength of the reinforcement is assumed to be available. This strength is computed by ignoring the creep-induced strength loss that is assumed for the design life of a wall based on static loading only. In other words, the residual strength value is calculated as the original available strength of the reinforcement immediately after the end of construction.

In order for the internal active wedge to be stable, the reinforcement layers must have adequate anchorage (pullout) capacity. The pullout capacity (T_{pull}) can be computed as:

$$T_{pull} = 2Cf^*\sigma_v L_e \quad (7)$$

Here, C is the coverage ratio of the reinforcement in the plane of the reinforcement and is equal to one for continuous sheet reinforcement (e.g., geogrid, woven geotextile). Parameter f^* is the interface shear coefficient and is a function of the reinforcement type and soil type, and for the case of steel strips, it will also be a function of depth. Parameter σ_v is vertical stress acting at the elevation of the reinforcement and L_e is the anchorage length. The anchorage length can be computed knowing the geometry of the internal active wedge. In Fig. 5 this wedge is shown as triangular shape which is the typical assumption for MSWs constructed with relatively extensible geosynthetic reinforcement materials. For steel reinforcement, the active wedge is assumed to be bilinear in shape with a constant distance from the back of the wall equal to $0.3H$ to a depth of $H/2$ below the crest of the wall and then tracing a straight line to the heel of the wall face thereafter. For MSWs constructed with select backfills, there is no evidence to suggest that the value of f^* should be less for the case of earthquake loading than for the static loading condition.

Rigorous analytical or numerical solution of the active Coulomb wedge problem for the case of addition seismic inertial forces shows that the orientation of the internal failure wedge (α_{AE})

Design of Mechanically Stabilized Walls (MSWs),

Fig. 6 Double integration method to calculate displacements in sliding block analysis

illustrated in Fig. 3 will decrease with increasing magnitude of k_h . This can lead to excessive reinforcement lengths. Conventional practice for geosynthetic reinforced walls is to limit this angle to the static loading value which is reasonably approximated using the Rankine solution $\alpha = \pi/4 + \phi/2$. Similarly, the bilinear wedge shape for steel-reinforced MSWs is assumed to be applicable to both static and dynamic loading cases. Pullout may be a concern at the top of the wall where vertical stress (σ_v) is low. The solution is to locally increase the length of these layers (L_c) to meet an acceptable factor of safety against this mode of failure.

Sliding Block Displacement Methods

A shortcoming of pseudo-static design and analysis methods is that they cannot be used to predict serviceability performance of a wall with respect to displacement. Sliding block displacement methods have been used for many years to estimate the displacement of earth structures during earthquake. This general approach is easily adaptable to failure limit states for MSWs where the failure surface is horizontal (see Fig. 2a, f). The first step is to find the critical acceleration, k_c , which is the value of k_h that will give a factor of safety of unity in the corresponding static factor of safety expression. The critical acceleration is then

applied to the horizontal ground acceleration record at the structure, and double integration is performed to calculate the cumulative displacement, as illustrated in Fig. 6. Specifically, the cumulative displacement is calculated by integrating those portions of the accelerogram that are above the critical acceleration and those portions that are below until the relative velocity between the sliding mass and the sliding base reduces to zero.

Dynamic Finite Element or Finite Difference Methods

MSWs are complex mechanical systems and this complexity is compounded when the structures are subjected to transient dynamic loading due to earthquake. Pseudo-static and displacement methods may be sufficient for simple structures, for stable ground conditions and MSWs in low seismic risk areas, and/or for preliminary design. Otherwise, more sophisticated analyses may be warranted using advanced dynamic finite element model or finite difference computer programs. Today commercially available computer programs offer the user a suite of constitutive models for the component materials and in some cases allow the user to implement their own constitutive models. In order to accurately model the soil in a MSW, it may be necessary to use nonlinear cyclic stress-strain models. The equivalent-linear

method (ELM) is one example. The ELM requires strain-dependent shear stiffness degradation curves and damping curves to capture the reduction of shear modulus of the soil and the increase in soil damping that occurs with increasing shear strain. These parameters can be found in published databases or from project-specific resonant column testing for small shear strain amplitudes and cyclic triaxial tests for larger strain amplitudes. Another important consideration for the correct numerical modeling of MSWs with polymeric reinforcement materials is the strain-rate-dependent stiffness of these materials. Often forgotten is that the stiffness of polymeric PP and HDPE reinforcement products increases significantly with rate of loading. Hence, stiffness values deduced from conventional laboratory tensile tests at low strain rates will underestimate the stiffness of the reinforcement during dynamic loading. Consequently, numerical-predicted reinforcement loads will be nonconservative for design (i.e., underestimated).

Additional Considerations

Frequency Response

The seismic response of MSWs of typical heights (say $H < 10$ m) can be dominated by the natural frequency of the structure. A recommended check of the response of any soil structure is the proximity of the natural (resonant) frequency of the system (f_ω) to the predominant frequency of the input acceleration record (f_1). An approximate upper-bound estimate of the natural frequency of a MSW structure can be computed from linear-elastic theory as:

$$f_\omega = V_s/4H = 1/4H \sqrt{\frac{G}{\rho}} \quad (8)$$

where V_s = shear-wave velocity of the soil back-fill, G = shear modulus, and ρ = density of the soil. Modifications to this formula are available in the literature to adjust this one-dimensional solution to the case of two-dimensional rectangular volumes to match the reinforced soil zone shape.

Factors of Safety and Load and Resistance Factor Design (LRFD)

The concepts introduced in this entry for seismic design of MSWs have been related to margins of safety using classical notions of factor of safety. In this approach, factor of safety is simply the ratio of resistance capacity to load. In North American practice, the factors of safety against the modes of failure identified in Fig. 2 are reduced to values that are typically 75 % of static values or as low as 1.1. The exception is the factor of safety for overstressing (rupture) for geosynthetic reinforcement products which is taken as unity for seismic design.

Modern US design codes for MSWs now adopt a load and resistance factor design (LRFD) approach (AASHTO 2012; FHWA 2009). Load factors are applied to each load term in a limit state function, and a single resistance factor is applied to the resistance term in the same function. The factors have been computed using rigorous reliability theory to satisfy an acceptable minimum target probability of failure or to give design outcomes with equivalent factors of safety to those using the conventional factor of safety approach. Load and resistance factors are different for seismic and static design consistent with the expectation that severe earthquakes are relatively rare events over the design life of a typical MSW. In Europe, a partial factor of safety approach is used in which partial factors are applied to material properties on the resistance side of each limit state function. At present, partial factors have not been updated for seismic design of MSW systems in the British code (BSI 2010). Eurocode guidelines are limited to a summary of the general approaches to the design and analysis of geotechnical soil structures.

Performance of MSWs During Earthquake

In recent years, surveys of MSW structures have been carried out in the Americas and in Japan after earthquakes. These surveys and project-specific case studies of reinforced soil walls after earthquake have demonstrated generally good behavior, and, where direct comparisons are available, they have behaved better than conventional gravity structures and at least as well as

traditional reinforced concrete structures (Koseki et al. 2006; Yen et al. 2011). Geosynthetic MSWs constructed with full-height panel facings for railway track embankments and bridge abutments (including bullet train lines) were virtually undamaged and exhibited good seismic resistance during the recent 11 March 2011 Great East Japan Earthquake compared with conventional unreinforced embankments (JGS 2011).

The reason for this good performance is that MSWs are generally more flexible than conventional walls. They are more forgiving of the uneven ground displacements that may occur due to surface faulting during an earthquake event. Importantly, the ductility of these systems has prevented collapse of structures during earthquakes so that adjacent structures, property, or persons were not put at risk even though supporting infrastructure (e.g., railway lines) was no longer in service. Where there have been detectable performance problems, these are typically related to inadequate details at the wall corners, the joints between full-height panels, and the wall top due to inadequate coping details or toppling of masonry concrete blocks.

In addition to field surveys, there is now a large body of results from centrifuge and 1-g gravity tests on model walls subjected to simulated earthquake loading using laboratory shaking tables. Overturning about the toe of a MSW structure is rare and can be safely omitted for the external stability design of MSW structures. Similarly, bearing capacity failure is unlikely and this mode of failure is not expected for walls built on competent foundations. Field surveys and laboratory shaking table tests have demonstrated that MSWs designed to satisfy current factors of safety for static design are typically stable at peak ground accelerations up to 0.4 g if the structures are seated on competent level ground below and in front of the walls and the walls support horizontal backslopes (Mikola and Sitar 2013). Consequently, for these scenarios additional earthquake-induced loads need not be considered in design. The explanation for this recommendation is that the static design of these structures is very conservative. Hence, these walls have sufficient excess load capacity

so that static designs do not need to be augmented for peak ground accelerations less than 0.4 g. Details of the conditions that meet this waiver can be found in the American Association of State Highway and Transportation Officials design guidelines (AASHTO 2012). For wall cases exceeding the 0.4-g criterion, more sophisticated analyses executed by experienced and knowledgeable design engineers will be required. Often this will include displacement methods and numerical modeling using commercial computer software programs that use dynamic finite element or finite difference methods.

Summary

Mechanically stabilized walls (MSWs) are a well-accepted technology to perform the earth retaining wall function in civil engineering earthwork applications. The design of these structures for earthquakes is most often based on conventional extensions of static wall design that are well known and accepted by geotechnical engineers. The performance of MSWs during earthquake loading has been excellent in most cases due to their relative flexibility compared to conventional gravity wall structures and their reserve load capacity due to conservatism in the static design of these structures.

Introduction

Over the last three decades, structural control has achieved significant progress. Structural control includes three categories: passive, active, and

semi-active. Among them, passive control systems are less expensive and have the advantage of not requiring an external source of power. The passive control systems consist basically on installing energy-dissipating devices (dampers) in the main structure, in order to increase its energy dissipation capacity and to prevent or limit the damage in the main structure (plastic deformations) in case of severe earthquakes. The use of seismic energy-dissipative devices for passive control is increasing exponentially in recent years for both new and existing buildings (Martelli 2006). The challenge now is to produce low-cost and effective dampers feasible for massive use in developing countries.

Several mechanisms have been used for passive energy dissipation: yielding of metals, phase transformation of metals, friction sliding, fluid orificing, and deformation of viscoelastic solids or liquids. The former is one of the most popular and there are a number of ways to induce the yielding of the metal. In the ADAS damper (Berman and Goel 1987), yielding is attained by subjecting metallic plates to out-of-plane bending. In the honeycomb damper (Kobori et al. 1992) or the slit damper (Benavent-Climent et al. 1998) a metallic plate with openings is subjected to in-plane shear deformations. Another popular damper is the so-called Buckling Restrained Brace (Chan and Albermani 2008), which consists on yielding a metal core subjected to axial deformations, preventing buckling under compressive loads.

A new type of hysteretic damper, called Web Plastifying Damper (WPD), was recently proposed by Benavent-Climent et al. (2011) that is based on subjecting the web of standard wide-flange or I shape sections to out-of-plane bending, to dissipate energy in seismic applications. Yielding the web under out-of-plane bending is a potential source of energy dissipation because: (i) the transition from the web-ends to the flanges has a smooth curve shape (preventing stress concentrations), and (ii) the union between flange and web is weld-free, which avoids uncertainties and imperfections associated with welding. This energy-dissipating device requires a very simple manufacturing process (cutting a wide-flange or I-section in short segments and drilling openings

Design, Testing, and Evaluation of the Web Plastifying Damper for the Aseismic Protection of Buildings,
Fig. 1 Details of a typical WPD

in the flanges for the bolts). Further, leftovers of wide-flange or I-sections can be employed. For these reasons, the new damping device is quite economic.

Hereafter, the new type of seismic damper is presented and the guidelines and formulae for its design are provided. The energy dissipative characteristics of the web of wide-flange sections are investigated experimentally, and a simple hysteretic model for representing the load–displacement curve under arbitrary deformations is presented.

Design of the Web Plastifying Damper

The WPD is installed in a frame structure as a conventional brace or diagonal bar. It is constructed by assembling short length segments of wide-flange or I-shaped sections and two steel bars that remain elastic and function as auxiliary elements. If the brace damper is subjected to forced deformations in the axial direction, the web of the wide-flange or I-shape section undergoes out-of-plane flexural deformations. Figure 1 shows a prototype of the WPD, where standard U-shaped steel sections have been used as auxiliary elements.

The relative displacement δ_y between flanges at yielding, the yielding load Q_y , and maximum load Q_B of a single segment of wide-flange or I-shaped section of length l , clear height of the web h , and web thickness t are given by:

$$\delta_y = \frac{f_y h^2}{2tE} \quad (1)$$

$$Q_y = \frac{lt^2 f_y}{2h} \quad (2)$$

$$Q_B = \frac{lt^2 f_B}{2h}. \quad (3)$$

In the above equations, f_y and f_B are the yield and maximum tensile stress of the steel, and E the modulus of elasticity. The axial yield strength Q_{Ty} and apparent maximum strength Q_B of a damper constituted of n wide-flange of I-shaped segments are given by:

$$Q_{Ty} = n \frac{lt^2 f_y}{2h} \quad (4)$$

$$Q_B = n \frac{lt^2 f_B}{2h} \quad (5)$$

By summing the δ_y and the axial elastic deformation of the steel bars that function as auxiliary elements, the total axial displacement of the brace damper at yielding, δ_{Ty} , is obtained. The later contribution can be approximated by $f_{aux}L/E$, where L is the total length of the brace damper and f_{aux} is the normal stress in the cross-section of the steel bar caused by the axial force Q_{Ty} , that is:

$$\delta_{Ty} = \frac{f_y h^2}{2tE} + \frac{f_{aux} L}{E} = \frac{1}{E} \left[0.5 f_y \left(\frac{h^2}{t} \right) + f_{aux} L \right] \quad (6)$$

From Q_{Ty} and δ_{Ty} , the axial stiffness K_T of the brace damper is given by:

$$K_T = \frac{Q_{Ty}}{\delta_{Ty}} = \frac{nl^3 f_y E}{f_y h^3 + 2thL f_{aux}} \quad (7)$$

In order to design a brace damper of given length L with target strength and yield

Design, Testing, and Evaluation of the Web Plastifying Damper for the Aseismic Protection of Buildings, Fig. 2 Test specimen

displacement, Q_{Ty} and δ_{Ty} , respectively, the following paths must be followed:

- Choose the type of steel and the stress level in the auxiliary elements f_{aux}
- Using Eq. 6 determine the required h^2/t
- Choose a commercial wide-flange or I-shape section that fits the required h^2/t
- Determine the value of the product nl to attain the target strength Q_{Ty} using Eq. 4
- Determine an appropriate combination of n and l , compatible with architectural constraints of the buildings
- Ensure that the following design requirements are fulfilled:

$$\frac{h}{t} > \frac{3\sqrt{3}}{4} \quad (8)$$

$$\left(\frac{t_f}{t}\right)^2 > \frac{3f_B}{4f_y} \quad (9)$$

Above requirements ensure that the WPD fails under out-of-plane flexural yielding of the web of the wide-flange or I-shape section, near the round-shaped transition zone from the web to the flanges (see Fig. 2).

Testing the Web Plastifying Damper

Six component tests were conducted to investigate the energy dissipation capacity and to characterize the hysteretic behavior of the WPD. Each test consisted in subjecting 90 mm length specimens cut from a single segment of a structural

wide-flange section of $140 \times 73 \text{ mm}^2$ (total depth $\times$ flange width) – referred to as the IPE-140 section hereafter – to different histories of imposed out of plane bending, until failure. Figure 2 shows the test specimen.

The mechanical characteristics of each test specimen, in terms of length l , the clear height of the web h , and the web thickness t are: $l = 90 \text{ mm}$, $h = 112 \text{ mm}$, and $t = 5.4 \text{ mm}$. The specimens were made of mild steel S275, with $f_y = 340 \text{ N/mm}^2$, $f_B = 441 \text{ N/mm}^2$ and $E = 2.1 \times 10^5 \text{ N/mm}^2$. Applying above equations, the lateral displacement δ_y , the load Q_y at yielding, and the apparent maximum lateral load Q_B of a single IPE-140 section damping device are $\delta_y = 1.88 \text{ mm}$, $Q_y = 3.98 \text{ kN}$ and $Q_B = 5.17 \text{ kN}$.

The only variable considered in the tests was the loading history. Patterns of cyclic displacements were applied to the specimens until they failed. Failure was assumed to occur at the onset of strength degradation under increasing forced displacements. The cyclic rate applied by the actuator was 1/80Hz. In the first, second, and third tests cycles of incremental amplitude were applied to the specimens, with the increment of amplitude in each consecutive cycle normalized by the yielding displacement δ_y being $\phi = 2$, $\phi = 5$ and $\phi = 10$, respectively. The specimens were subjected to cycles of constant amplitude in the fourth and fifth tests; the amplitude normalized by the yielding displacement δ_y was $\Delta = 20$ and $\Delta = 30$, respectively. The loading protocol ATC-24 developed by the Applied Technology Council (Applied Technology Council 1992) was applied to the sixth specimen. This protocol

Design, Testing, and Evaluation of the Web Plastifying Damper for the Aseismic Protection of Buildings, Fig. 3 Decomposition of a Q - δ curve: (a) Q - δ curve; (b) skeleton part; (c) Bauschinger part

consists of several sets of three cycles; the amplitude of the cycles is constant within each set but it is increased every consecutive set of cycles, following the sequence $0.5\delta_y, 0.75\delta_y, 1.0\delta_y, 2\delta_y, 3\delta_y, 4\delta_y$ and so on.

Hysteretic Behavior

Figure 3a shows a typical load–displacement Q - δ hysteretic curve obtained from the test. It can be seen that the WPD has stable hysteretic behavior and high energy dissipation capacity.

Ultimate Energy Dissipation Capacity

Following the procedure formerly proposed by Kato et al. (1973) a Q - δ hysteretic curve such that is shown in Fig. 3a can be decomposed into: (i) the segments controlled by the Bauschinger effect, so-called “Bauschinger part”; (ii) the segments controlled by the strain-hardening phenomena, so-called “skeleton part”; (iii) and the unloading paths, so-called “unloading segments”. It has been shown (Kato et al. 1973) that the curve obtained by connecting subsequently the segments of the skeleton part coincides with the relation obtained from a monotonic test.

The scheme proposed by Kato et al. (1973) was applied for decomposing the Q - δ hysteretic curves obtained during the cyclic tests, as illustrated in Fig. 3a, b, and c. In these figures, the segments 0–1, 5–6, 11–12, 17–18 in the positive, and 2–3, 8–9, 14–15 in the negative domain are the paths that exceed the load level attained by the preceding cycle in the same domain of loading. Connecting these paths sequentially, the two curves called “skeleton part” (Fig. 3b) are obtained. These curves can be approximated by a three-segment curve that is shown with dash and dot lines in Fig. 3b. The trilinear approximation is defined by the yielding load, Q_y , the yielding displacement, δ_y , the first and second plastic stiffnesses K_{p1} and K_{p2} ($K_{p1} \geq K_{p2}$), and the load Q_B corresponding to the transition point from K_{p1} to K_{p2} . The unloading paths are the segments 1–2, 6–7, 12–13, 18–19, 3–4, 9–10, and 15–16. The slope of the unloading paths coincides with the initial elastic stiffness $K_e (=Q_y/\delta_y)$. In Fig. 3b, $s\delta_u^+$ and $s\delta_u^-$ are the plastic deformation accumulated in each skeleton curve when the WPD device fails. On the other hand, $s\delta_B$ is the plastic deformation accumulated

in the approximate trilinear skeleton curve at $Q = Q_B$. The area enveloped in Fig. 3b for each domain of loading by the skeleton curve is called hereafter sW_u^+ and sW_u^- . The segments 4–5, 10–11, and 16–17 in the positive domain and 7–8 and 13–14 in the negative domain of loading begin at $Q = 0$ and terminate at the maximum load level previously attained in

preceding cycles in the same loading domain; they constitute the so-called “Bauschinger part” (Fig. 3c). The sum of the area enveloped by the Bauschinger part for each domain of loading will be referred to as BW_u^+ and BW_u^- .

In addition, sW_u^+ , sW_u^- , BW_u^+ , BW_u^- , $s\delta_u^+$ and $s\delta_u^-$ can be expressed in a nondimensional by,

$$s\bar{\eta}^+ = \frac{sW_u^+}{Q_y\delta_y}; \quad s\bar{\eta}^- = \frac{sW_u^-}{Q_y\delta_y}; \quad B\bar{\eta}^+ = \frac{BW_u^+}{Q_y\delta_y}; \quad B\bar{\eta}^- = \frac{BW_u^-}{Q_y\delta_y}; \quad ep\bar{\eta}^+ = \frac{s\delta_u^+}{\delta_y}; \quad ep\bar{\eta}^- = \frac{s\delta_u^-}{\delta_y}, \quad (10)$$

Next, the following ratios are defined:

$$\begin{aligned} s\eta &= |s\bar{\eta}^+| + |s\bar{\eta}^-|; \quad B\eta \\ &= |B\bar{\eta}^+| + |B\bar{\eta}^-|; \quad ep\eta \\ &= |ep\bar{\eta}^+| + |ep\bar{\eta}^-|; \quad \eta = s\eta + B\eta \end{aligned} \quad (11)$$

$ep\eta$ denotes the apparent ultimate cumulative plastic deformation ratio on the skeleton part; $s\eta$ is the ultimate cumulative plastic deformation ratio on the skeleton part; $B\eta$ is the ultimate cumulative plastic deformation ratio on the Bauschinger part; η is the total ultimate cumulative plastic deformation ratio. η represents in nondimensional form the total energy dissipated by the damper until failure, i.e. $W_u (= sW_u^+ + sW_u^- + BW_u^+ + BW_u^-)$.

Table 1 shows the values of the parameters defined above obtained from each test. It can be seen in the table that the total energy dissipated by the WPD as expressed by η , and the distribution of this energy between the skeleton and the

Bauschinger parts (i.e., $B\eta/s\eta$) depend on the loading pattern. If the WPD is subjected to cycles of small constant amplitude (i.e., the loading pattern with $\Delta = 20$) or to cycles whose amplitude grows in small increments (i.e., the loading patterns ATC-40 or with amplitude $\phi = 2$), η and $B\eta/s\eta$ are larger than when applying cycles of large constant amplitude (i.e., the loading pattern with $\Delta = 30$) or than cycles whose amplitude enlarges in large increments (i.e., the loading pattern with $\phi = 10$).

It can be seen that the relation between the values $ep\eta$ and $B\eta$ shown in Table 1 is almost linear and can be formally expressed by:

$$B\eta = a_{ep}\eta + b. \quad (12)$$

The value of parameters a and b for the WPDs tested are $a = -12$ and $b = 1140$. It has been shown in previous research that while the relation between $B\eta$ and $ep\eta$ is linear irrespective of the steel type, the values of a and b depend on the

material properties and must be determined for each type of steel. a and b can be obtained by testing only two specimens under different patterns of cyclic loading.

As for the skeleton part, the approximated trilinear curve shown in Fig. 3b can be normalized by dividing the abscissa by δ_y given by Eq. 1, and the ordinate by Q_y given by Eq. 2. The resulting values of the normalized plastic stiffness $k_{p1} = K_{p1}/(Q_y/\delta_y)$, and $k_{p2} = K_{p2}/(Q_y/\delta_y)$ for the WPD tested, are $k_{p1} = 1/5$ and $k_{p2} = 1/30$. Now, a new parameter τ_B is defined to characterize the normalized trilinear skeleton curve as

$\tau_B = Q_B/Q_y$. Using these parameters, the energy dissipated on the skeleton part expressed in nondimensional form by $s\eta$ can be related to $ep\eta$ assuming that the skeleton curves in the positive and negative domains of loading are equal and that $|_{ep\eta}| = |_{ep\eta}| = |_{ep\eta}| = 0.5ep\eta$:

$$\text{for } ep\eta \leq \frac{2(\tau_B - 1)(1 - k_{p1})}{k_{p1}} : \quad (13)$$

$$s\eta = 0.25ep\eta^2 \frac{k_{p1}}{1 - k_{p1}} + ep\eta$$

$$\text{for } ep\eta > \frac{2(\tau_B - 1)(1 - k_{p1})}{k_{p1}} : \quad (14)$$

$$s\eta = \frac{(\tau_B^2 - 1)(1 - k_{p1})}{k_{p1}} + \left(\frac{ep\eta}{2} - \frac{(\tau_B - 1)(1 - k_{p1})}{k_{p1}} \right) \left[2\tau_B + \frac{k_{p2}}{(1 - k_{p2})} \left(\frac{ep\eta}{2} - \frac{(\tau_B - 1)(1 - k_{p1})}{k_{p1}} \right) \right]$$

By adding Eqs. 12, 13, and 14, the ultimate energy dissipation capacity in terms of the nondimensional ratio η is obtained as follows:

$$\text{for } ep\eta \leq \frac{2(\tau_B - 1)(1 - k_{p1})}{k_{p1}} : \quad (15)$$

$$\eta = 0.25ep\eta^2 \frac{k_{p1}}{1 - k_{p1}} + ep\eta(1 + a) + b$$

$$\text{for } ep\eta > \frac{2(\tau_B - 1)(1 - k_{p1})}{k_{p1}} : \quad \eta = \frac{(\tau_B^2 - 1)(1 - k_{p1})}{k_{p1}} + \left(\frac{ep\eta}{2} - \frac{(\tau_B - 1)(1 - k_{p1})}{k_{p1}} \right) \left[2\tau_B + \frac{k_{p2}}{(1 - k_{p2})} \left(\frac{ep\eta}{2} - \frac{(\tau_B - 1)(1 - k_{p1})}{k_{p1}} \right) \right] + aep\eta + b \quad (16)$$

Numerical Model for Characterizing the Hysteretic Behavior of the WPD

The load–displacement relationship of the WPD under an arbitrary cyclic loading pattern can be predicted with a simple hysteretic model, and a procedure for predicting its failure. In this hysteretic model, the shape of the skeleton part and the shape of each segment of the Bauschinger are determined as follows.

For characterizing the shape of the skeleton part, the trilinear idealization proposed above is adopted. The shape of the Bauschinger parts is studied next. Focusing on Fig. 3a, consider for example that under a given loading history, the WPD has covered the path 0-1-2-3-4-5-6-7-8-9-10, and an approximation for the Bauschinger segment 10–11 located in the positive loading domain is sought. The ordinate at the origin of the segment (i.e., point 10) is $Q = 0$, and the

ordinate at the end (i.e., point 11) is known because it coincides with the maximum force Q_m attained in the skeleton part in previous cycles of deformation in the same domain of loading (i.e., the ordinate at point 6 which is referred to as $Q_m = Q_6$ in Fig. 3a). The Bauschinger segment 10–11 can be further approximated with a bilinear curve determined by three parameters: (i) the stiffness of the first line; (ii) the displacement ${}_B\delta$ of the segment (i.e., ${}_B\delta_2^+$ in Fig. 3c for the example segment 10–11); and (iii) the ordinate of the intersection point of the two lines, which will be expressed as a fraction α of the maximum force attained in the skeleton part in previous cycles of deformation in the same domain of loading αQ_m (i.e., αQ_6 for the example segment 10–11). For the WPD, and based on the results of the test, these parameters can be set as follows: (i) the first stiffness is taken equal to the initial elastic stiffness K_e ; (ii) ${}_B\delta$ is taken as a fraction β of the displacement accumulated in the skeleton part $\sum {}_S\delta$ up to the start of the Bauschinger segment under consideration (i.e., for the example segment 10–11, ${}_B\delta_2^+ = \beta\{|_S\delta_1^+| + |_S\delta_1^-| + |_S\delta_2^+| + |_S\delta_2^-|\}$); and (iii) the value of α is determined so that the area (i.e., the dissipated energy) under the Bauschinger segment obtained from the test and the area under the approximated bilinear curve are equal. Based on the test results, for the WPD the following values can be adopted: $\alpha = 0.66$ and $\beta = 0.61$.

Once the shape of the skeleton part and the Bauschinger part are determined by the parameters Q_y , Q_B , δ_y , k_{p1} , k_{p2} , α and β , the hysteretic curve of the WPD under an arbitrary history of displacements can be constructed as follows. The first time the damper is loaded in a given domain (positive or negative), the proposed model considers that the Q - δ relationship follows the skeleton curve. Referring to Fig. 3a, consider for example that, first – starting from point 0 – the damper is deformed an amount ${}_S\delta_1^+$ in the positive domain; it will follow the skeleton curve moving from point 0 to 1. At point 1 the deformation accumulated on the skeleton part is $\Sigma_S\delta = |_S\delta_1^+|$ and the corresponding force attained

is Q_I . If the damper is unloaded at point 1, the Q - δ curve will follow the unloading line of stiffness K_e ($=Q_y/\delta_y$) until point 2. If the WPD is now loaded in the opposite domain of loading, the Q - δ curve follows the skeleton curve, from point 2 to 3. $\Sigma_S\delta = |_S\delta_1^+| + |_S\delta_1^-|$ is the deformation accumulated on the skeleton part at point 3. If the damper is unloaded at point 3 it will again follow a line of stiffness K_e until point 4. Reloading the damper in the positive domain, the Q - δ curve will follow a Bauschinger path whose amplitude ${}_B\delta$ is ${}_B\delta_1^+ = \beta\{|_S\delta_1^+| + |_S\delta_1^-|\}$. Within this Bauschinger path, initially the Q - δ curve follows a line of stiffness K_e until the point of ordinate αQ_I ; from here, the Q - δ curve follows a line oriented to a point determined by ${}_B\delta_1^+$ and Q_I . Following this rule, the complete hysteretic curve under arbitrary loading can be constructed until failure.

For the prediction of the failure of the WPD, deformation accumulated on the skeleton curve in each step i of the loading process, $\Sigma_S\delta_i$, and the total energy W_i dissipated by the WPD up to this step, must be monitored. The corresponding ratios ${}_{ep}\eta_i$ and η_i at step i are: ${}_{ep}\eta_i = \Sigma_S\delta_i/\delta_y$ and $\eta_i = W_i/(Q_y\delta_y)$. Failure is assumed to occur when this point reaches the “failure line” defined by Eqs. 15 and 16 (Benavent-Climent 2007).

Summary

A new type of seismic damper based on plastifying the web of short length segments of wide-flange or I-shaped steel sections under out-of-plane bending is presented. The damper can be installed in a frame like a conventional brace. The damper device was tested to characterize its hysteretic behavior and ultimate energy dissipation capacity. The results of the tests indicate that the seismic damper has stable restoring force characteristics and high energy dissipation capacity. Further, the load–displacement curve of the damper under arbitrarily applied cyclic load can be easily predicted with a simple numerical model. Also, its ultimate energy dissipation

capacity and the proximity to failure can be anticipated with a procedure that takes into account the influence of the loading path.

Borehole seismometers; Direct burial installation; Posthole seismometers

Introduction

This entry reviews the topic of downhole seismometers. The entry is split into three sections. The first section reviews the different types of downhole seismometers. The second section provides an overview of seismic noise sources and their impact on downhole installations. The last section discusses the downhole installation methods.

There are three main motivations for deploying seismometers in a downhole environment. The first is to provide quieter seismic noise environment to improve signal-to-noise ratios. The second motivation is to lower the cost of deployment of a seismic station. The third motivation is to reduce the environmental impact and land use costs by minimizing the physical footprint of a seismic station.

Downhole Seismometer Types

Seismometers can be categorized by the installation environment into three broad classes of instruments, surface (or vault) seismometers, ► [ocean bottom seismometers](#) (OBS), and downhole seismometers. Downhole seismometers are seismometers that are designed for installation below the surface, ocean bottom seismometers are designed for deployment underwater to depths of 7,000 m or more, and vault seismometers are designed for installation in seismic vaults at or near the surface. The construction of vaults is described in some detail in the “► [Principles of Broadband Seismometry](#)” entry.

Although these three classes of seismometers are markedly different in appearance, the internal sensing transducers and associated electronics are typically similar in design and performance. The difference is in the packaging and topology: in vault seismometers, the three axes are normally side by side, in downhole seismometers the axes are often stacked vertically, and in OBS seismometers either topology can be utilized. Typically, downhole seismometers are packaged in tall cylindrical stainless steel

Downhole Seismometers,

Fig. 1 Posthole and vault seismometers

pressure tubes and are watertight to a depth of 50–1,000 m. Vault seismometers are normally not designed for continuous submersion in water. The diameter of a downhole seismometer is minimized to enable the seismometer to fit down narrow boreholes. The diameter of a vault seismometer is not as critical as a downhole seismometer, and vault seismometers are typically shorter and wider for stability (see Fig. 1).

Vault seismometers are usually leveled by hand using a reference bubble level and adjusting three leveling feet. Downhole seismometers are normally not accessible for manual leveling and have automatic leveling mechanisms where leveling is required.

Downhole seismometers can be further broken down into two different instrument types, namely, borehole seismometers and posthole seismometers.

Borehole seismometers are downhole seismometers that are designed for deployment in steel-cased deep boreholes. These seismometers

typically include a holelock assembly as part of the instrument. A holelock is used to mechanically support and connect the seismometer to the borehole casing. It includes an actuator or a passive spring that pushes the entire seismometer against the side of the borehole with a substantial force. This force holds the seismometer rigidly in place and prevents the seismometer sliding down the hole.

A posthole seismometer is a downhole seismometer that does not include a holelock and is designed for direct burial or installation in shallower, uncased holes, known as postholes. A posthole seismometer is designed to be installed in sand at the bottom of a posthole. The sensor will typically also have three fixed feet, which can be useful in side-by-side testing on a pier, or placement at the bottom of a cased hole, as long as that surface is reasonably hard and level. These seismometers are designed for holes up to 50 m deep and may not have the underwater pressure rating of a borehole

seismometer. Furthermore, a posthole seismometer's drivers and power supplies may not support the cable lengths required for a borehole seismometer.

A downhole seismometer can be a single-component seismometer, meaning that the seismometer only measures vertical motion or that it can be a three-component seismometer which measures vertical, north–south, and east–west motion. Three-component seismometers are also known as triaxial seismometers.

An important parameter in selecting a downhole seismometer is the self-noise level of the instrument. The self-noise of a seismometer defines the limit of the instrument's ability to resolve ground motion. The self-noise of a seismometer is often graphed with respect to the minimum earth noise as defined by the new low-noise model (NLNM) (Peterson 1993). Although a self-noise graph provides a comprehensive view of seismometer performance over frequency, the long-period performance of an instrument is typically the limiting parameter of the self-noise. This is because all seismometers have self-noise lines that steadily curve upward at long periods.

Seismometers can be further categorized by the lower corner frequency (–3 dB point) of the amplitude frequency response of the instrument. Geophones have lower corner frequencies from 1 to 40 Hz. Short-period seismometers have lower corner frequencies from 1 to 4 Hz, and broadband seismometers have lower corner frequencies from 0.027 to 1 Hz. Broadband seismometers typically have lower noise floors over wider bandwidths than short-period seismometers, and short-period seismometers are typically quieter than geophones. Accelerometers are approaching the performance levels of some geophones and short-period seismometers and can be considered for downhole applications too.

Nevertheless, in most downhole applications today, broadband seismometers are typically used since they can measure all three components of motion, are quieter instruments, and can be realized in packages that fit downhole. Broadband seismometers are more challenging to install downhole than short-period seismometers

due to lower tilt tolerances. This entry will focus on broadband downhole seismometers and their installation. However, many of the installation techniques and challenges presented in this entry apply to short-period seismometers, accelerometers, and geophones in varying degrees.

Leveling

In order for a seismometer to measure true vertical and north–south, east–west horizontal motion, the verticality error due to the as-drilled borehole must be compensated for along with the north–south orientation. The methods of north–south orientation will be discussed in a later section (see section “[Water Egress](#)”), with this section focusing on leveling. Since a downhole seismometer cannot be leveled manually because it is down a borehole or posthole, downhole seismometers have automatic leveling mechanisms that can adjust the sensing elements or axes to measure true vertical and horizontal motion.

The leveling range of a borehole seismometer is typically 5° to cover the range of verticality error due to the drilling. Some downhole seismometers have wider leveling ranges, but this is only needed in special situations.

Leveling mechanisms in seismometers are challenging to design due to the space constraints inside the seismometer, the need to have high fidelity coupling to ground motion, and the need to maintain a design that is not subject to spontaneous micro-mechanical movements. Different instrument designers have taken different approaches to designing leveling mechanisms for seismometers.

There are four main methods for leveling sensing axes within a seismometer, namely, gimbal leveling, horizontal axis leveling, mainspring adjustment, and electronic centering. Each of these methods has benefits and drawbacks that a user should be aware of in selecting a downhole seismometer. Some of the drawbacks relate to the axis topology within the seismometer. More details will be given below.

Within a triaxial seismometer, there are three sensing components or axes which measure motion in three orthogonal directions. These

Downhole Seismometers, Fig. 2 Axis orientations for XYZ and UVW topologies

axes can be configured in a familiar XYZ topology wherein X measures east–west motion, Y measures north–south motion, and Z measures vertical motion. The axes can also be configured in a Galperin or symmetric triaxial topology. In this topology the three axes are tilted at 54.7° from horizontal plane and 120° apart around the vertical axis. These axis directions are known as UVW, wherein U is 52.5° elevation, north 90° west azimuth; V is 54.7° elevation, north 30° east; and W is 54.7° elevation, north 120° east azimuth (Graizer 2009). The symmetric triaxial topology is an orthogonal arrangement where coordinate system rests on its corner (see Fig. 2). The transformation between the UVW coordinate system and the XYZ coordinate system is shown below:

$$\begin{bmatrix} u \\ v \\ w \end{bmatrix} = \frac{1}{\sqrt{6}} \cdot \begin{bmatrix} 2 & 0 & \sqrt{2} \\ -1 & \sqrt{3} & \sqrt{2} \\ -1 & -\sqrt{3} & \sqrt{2} \end{bmatrix} \cdot \begin{bmatrix} x \\ y \\ z \end{bmatrix}$$

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \frac{1}{\sqrt{6}} \cdot \begin{bmatrix} 2 & -1 & -1 \\ 0 & \sqrt{3} & -\sqrt{3} \\ \sqrt{2} & \sqrt{2} & \sqrt{2} \end{bmatrix} \cdot \begin{bmatrix} u \\ v \\ w \end{bmatrix}$$

Mathematically, leveling is the rotation of the seismometer axes about the X-axis and Y-axis

only. Rotation about the Z-axis is not handled by the leveling system. Z-axis rotations of a seismometer align the seismometer to true north. This will be discussed separately. A basic rotation of angle θ about the X-axis can be written in 3×3 matrix form:

$$R_x(\theta) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{bmatrix} \quad (1)$$

Similarly, a single rotation of angle α about the Y-axis is

$$R_y(\alpha) = \begin{bmatrix} \cos \alpha & 0 & \sin \alpha \\ 0 & 1 & 0 \\ -\sin \alpha & 0 & \cos \alpha \end{bmatrix} \quad (2)$$

The leveling process is the combination of the two rotations and can be written as

$$R_t = R_x(\theta) \cdot R_y(\alpha) \quad (3)$$

$$R_t = \begin{bmatrix} \cos \alpha & 0 & \sin \alpha \\ \sin \theta \sin \alpha & \cos \theta & -\sin \theta \cos \alpha \\ \cos \theta \sin \alpha & \sin \theta & \cos \theta \cos \alpha \end{bmatrix} \quad (4)$$

If the starting orientation of the seismometer axes is the vector, $X'Y'Z'$, and the leveled position is XYZ, then it can be written:

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = R_t \cdot \begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} \quad (5)$$

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} \cos \alpha & 0 & \sin \alpha \\ \sin \theta \sin \alpha & \cos \theta & -\sin \theta \cos \alpha \\ \cos \theta \sin \alpha & \sin \theta & \cos \theta \cos \alpha \end{bmatrix} \begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} \quad (6)$$

Expanding these equations results in:

$$x = x' \cos \alpha + z' \sin \alpha \quad (7)$$

$$y = x' \sin \theta \sin \alpha + y' \cos \theta - z' \sin \theta \cos \alpha \quad (8)$$

$$z = x' \cos \theta \sin \alpha + y' \sin \theta + z' \cos \theta \cos \alpha \quad (9)$$

The Y-component is a more complicated expression (Eq. 8), but that is the outcome of the order of the rotations. Changing the order of the rotations, namely,

$$R_t = R_y(\alpha) \cdot R_x(\theta) \quad (10)$$

results in the following expression for the Y-component:

$$y = y' \cos \theta - z' \sin \theta \quad (11)$$

Notice this equation has the same form as the X-component in Eq. 7, so for conceptualizing, this form can be used for both the X-component and Y-component.

Equations 7, 8, and 9 are important because some leveling methods do not actually level the seismometer axes. This results in the seismometer not outputting a true XYZ signal, but rather an XYZ as defined by Eqs. 7, 8, and 9 where an axis output is mixed with signals from the other two axes. These equations will be referred to as each leveling method is discussed in detail.

Gimbal Leveling

With gimbal leveling, there is a leveling platform on which all three seismometer axes are mounted. The seismometer axes are orthogonal to one another in both a symmetric triaxial and a horizontal-vertical topology, and the seismometer axes are fixed to the platform. The platform is leveled around the X and Y axes to eliminate tilt in the X and Y directions. Typically, motorized adjusters are used for leveling in the two directions. There are some passive leveling designs that rely on gravity to shift the gimbal to level using a mass under the gimbal. The seismometer axes can be stacked vertically or placed side by side on the leveling platform. Once the gimbal platform is leveled, the seismometer axes would need to be mass centered to eliminate any residual leveling error and to correct for temperature and spring relaxation. This is a more complex design as compared to the other methods, but it is more accurate in that the seismometer is outputting true vertical and horizontal signals. Referring to

Eqs. 7, 8, and 9, the angles θ and α are zero after leveling, and the three equations simplify to:

$$x = x'$$

$$y = y'$$

$$z = z'$$

Horizontal Axis Leveling

The horizontal axis leveling method is a variation of gimbal leveling where the vertical axis is fixed and not leveled, and the two horizontal axes are leveled in one direction only. This method can only be used on XYZ topology seismometers. It cannot be used in symmetric triaxial seismometers because it would affect the mixing ratios when converting from UVW to XYZ. Referring to Eqs. 7, 8, and 9 again, the vertical axis is fixed in position, so Eq. 9 describes the Z-component signal. The east-west axis or X-axis is leveled about the Y-axis, so Eq. 7 with α equal to zero holds. Lastly, the north-south axis or Y-axis is leveled about the X-axis, so Eq. 8 with θ equal to zero describes the Y-axis signal:

$$x = x' \cos \alpha + z' \sin \alpha, \alpha = 0$$

$$x = x'$$

$$y = x' \sin \theta \sin \alpha + y' \cos \theta - z' \cos \theta \cos \alpha, \theta = 0$$

$$y = y'$$

$$z = x' \cos \theta \sin \alpha + y' \sin \theta + z' \cos \theta \cos \alpha$$

With this leveling method, the X- and Y-components measure true X and Y motions, respectively, but the Z-component does not measure true Z motion. This is not as bad as it seems as the angles are small. Substituting a typical maximum tilt range of 5° in two directions results in:

$$\alpha = 5^\circ, \theta = 5^\circ$$

$$z = x' \cos (5) + y' \sin (5) + \cos (5)$$

$$z = 0.087x' + 0.087y' + 0.992z'$$

The vertical sensitivity is reduced by 0.76 % which is not much at all given that it is hard to calibrate a seismometer to better than 1 %. The Z signal also has X- and Y-components mixed in, but at a level ten times smaller than the Z-component. Expressed a different way, there is a loss of orthogonality between the axes. Herein lie the downsides of this method, the loss of orthogonality between axes resulting in the mixing of the Z-axis by X- and Y-components. If the tilt angles were known, then the vertical axis could be corrected after the measurement, but typically the tilt angles are not recorded so it cannot be corrected.

The main problem with this method is that the horizontal and vertical ground motions do not have the same magnitudes at long periods. Long-period horizontal signals are affected by tilt noise, which result in the apparent horizontal ground motion being much larger than the vertical. It is common for horizontal components to have amplitudes 20–50 dB higher at long periods than vertical components. With these levels, the horizontal components mixed into the vertical become significant and can swamp out the vertical signal at long periods. The user needs to be careful about how much tilt noise there is on the horizontals and the degree of tilt of the sensor. This complicates the deployment and places a burden of understanding on the user.

The primary benefit of this method is that it is simpler and less expensive to realize in a seismometer than gimbal leveling. This is because axes in downhole seismometers are typically stacked vertically due to space constraints on the diameter of the borehole. It is challenging to level three axes stacked together, so each axis is leveled individually. If each axis was leveled individually in the X and Y directions, there would need to be six leveling actuators in all: three axes times two directions. The horizontal axis leveling method only requires two leveling actuators, one on the X-axis and one on the Y-axis. There is a saving of four leveling actuators, hence the cost benefit.

Mainspring Adjustment

The mainspring adjustment method can be used in symmetric triaxial seismometers. This method does not actually involve leveling any part of the seismometer. Instead it compensates for the seismometer being off-level by adjusting the tension in the mainspring of the seismometer. All inertial sensors see an apparent horizontal acceleration when they are tilted. For small angles the apparent horizontal acceleration H corresponding to a tilt θ in radians is simply

$$H = g_0 \theta$$

where $g_0 = 9.8 \text{ m/s}^2$ is the acceleration due to gravity.

The equilibrium position is maintained by adjusting the tension in the mainsprings of each of the axes to exactly compensate for this apparent acceleration. The tension in the mainspring is adjusted by means of an actuator connected to the mainspring. Many seismometers already have a mainspring actuator to compensate for variations in the elastic modulus with temperature. Expanding the functionality of this actuator to include leveling does not require any more components so there is no impact on cost. However, there are trade-offs in the design which limit the usefulness of this approach.

There is a limit to how far a mainspring can be adjusted due to the geometry and size of a seismometer axis. In addition, with active broadband seismometers, there is a trade-off between mainspring adjustment leveling range and the noise floor of the seismometer due to noise in the seismometer feedback electronics. A low-noise floor seismometer using mainspring adjustment cannot have the required leveling range. A broadband seismometer with a high noise floor would be able to have the required leveling range, so this method is limited to high-noise floor seismometers.

For this method of leveling, Eqs. 7, 8, and 9 apply:

$$x = x' \cos \alpha + z' \sin \alpha \quad (7)$$

$$y = x' \sin \theta \sin \alpha + y' \cos \theta - z' \cos \theta \cos \alpha \quad (8)$$

$$z = x' \cos \theta \sin \alpha + y' \sin \theta + z' \cos \theta \cos \alpha \quad (9)$$

Downhole Seismometers, Table 1 Comparison of leveling methods

Leveling method	Maintains orthogonality	True leveling	Cost	Compatibility
Gimbal leveling	Yes	Yes	High	All
Horizontal axis leveling	No	Partial	Medium	XYZ only
Mainspring adjustment	Yes	No	Low	UVW only
Electronic centering	Yes	No	Low	Active only

The seismometer axes are fixed in orthogonal positions within the seismometer, so there is no loss of orthogonality, but the XYZ components do not measure true vertical and horizontal signals.

This method of leveling is less costly to implement, but it is limited to higher-noise seismometers.

Electronic Centering

Electronic centering can only be implemented in force balance seismometers. With this method, the electromagnetic coil circuit known as a forcing coil is used to hold the inertial mass in the equilibrium position and counterbalance change in the gravity vector. Any change in the apparent horizontal acceleration due to gravity is compensated by the forcing coil and electronic feedback. As an axis is tilted, the current in the coil changes which changes the force on the inertial mass. For a horizontal axis, the apparent acceleration H produced is related to the feedback current I , motor constant H , and boom mass M by

$$H = \frac{G}{M} I$$

This method preserves the orthogonality of the axes as the axes are in fixed positions and again, Eqs. 7, 8, and 9 apply, so the XYZ components are not true verticals and horizontals. This is the same as the mainspring adjustment method.

This method has a few disadvantages. The seismometer consumes more power since it is the forcing coil current that is counterbalancing the gravity vector now. In addition, inertial mass must be small to keep the current low and still achieve a wide tilt range, which results in higher levels of Brownian noise (see “► [Principles of Broadband Seismometry](#)”).

There are a number of advantages of this method. There are no leveling actuators or mainspring adjustment actuators, making the design more reliable and lower in cost. Depending on the lower corner frequency of the seismometer (see “► [Principles of Broadband Seismometry](#)”), the seismometer can have a wide leveling range of up to 10° .

Downhole Seismometer Selection

There are a number of criteria to consider in selecting a downhole seismometer. These include self-noise floor and axis topology, the cost, the leveling method, the leveling range, the type of seismometer, the physical dimensions of the seismometer, and the reliability and consistency of the seismometer.

The first item to consider in the selection process is the self-noise floor of the seismometer. The choice should depend on the noise environment that the sensor will be deployed in and on nature of the application. Ideally, site noise should be the limiting factor in the overall station noise, not seismometer self-noise.

However, the performance needs to be balanced with the cost of the instrument. Instruments with lower self-noise cost more than those with higher levels of self-noise. It is up to the user to trade off performance with cost for their application.

For the axis topology, the symmetric triaxial topology is particularly advantageous in the downhole environment due to the ease of differentiating between installation- and sensor-related noise (see “► [Symmetric Triaxial Seismometers](#)”). The four leveling methods each have cost and performance trade-offs which are summarized in Table 1.

For high-performance broadband seismometers, the most suitable leveling method is the

Downhole Seismometers, Table 2 A sample of downhole broadband seismometers available on the market in 2013

Seismometer name	Manufacturer	Lower corner frequency	Axis topology	Leveling method	Leveling range
Trillium 120 Borehole	Nanometrics	120 s	Symmetric triaxial	Gimbal	$\pm 5^\circ$
Trillium Posthole	Nanometrics	120 s	Symmetric triaxial	Gimbal	$\pm 5^\circ$ standard $\pm 10^\circ$ optional
Trillium Compact Posthole	Nanometrics	120 s	Symmetric triaxial	Electronic centering	$\pm 2.5^\circ$ $\pm 10^\circ$
KS-54000	Geotech	360 s	XYZ	Unknown	$\pm 10^\circ$
KS-2000BH	Geotech	120 s (standard)	XYZ	Unknown	$\pm 15^\circ$
CMG-3TB	Guralp	120 s	XYZ	Horizontal axis leveling	$\pm 3^\circ$ standard $\pm 10^\circ$ optional
CMG-40T-B	Guralp	60 s (standard)	XYZ	Electronic centering	$\pm 8^\circ$
CMG-Flute	Guralp	60 s (standard)	XYZ	Mainspring adjustment	$\pm 12^\circ$
STS-5A	Streckeisen	120 s	Symmetric triaxial	Gimbal	$\pm 5^\circ$

gimbal leveling as it does not compromise the quality of the data while maintaining orthogonality. The next most suitable method is horizontal axis leveling. Although the data will be neither as accurate nor as orthogonal, there are cost benefits to such an approach. Mainspring adjustment and electronic centering are best reserved for higher-noise, lower-cost seismometers.

For the leveling range, the user needs to ensure that the seismometer has sufficient leveling range to cover their deployment conditions. Insisting on a larger leveling range than needed unnecessarily limits the choice of seismometer. Most downhole applications do not require large leveling ranges.

The type of seismometer, namely, whether it is a borehole or posthole type, will be determined by the type of installation (see section “[Types of Installations](#)”). Borehole seismometers tend to cost more than posthole seismometers but can be deployed in deeper holes.

The user needs to ensure that the seismometer will fit into the posthole or borehole that has been drilled. Deeper holes tend to have smaller diameters to reduce the cost per meter of drilling; hence a narrower diameter instrument may be required.

Lastly, a user needs to consider the reliability and consistency of a seismometer. Some seismometers are more reliable than other

seismometers due to factors in the design and the quality of the manufacturing. The consistency of the seismometer refers to the spread in the self-noise floor over time and from instrument to instrument. This can best be assessed by huddle testing at least three instruments over a period of time (Sleeman et al. 2006). There are a number of published papers on self-noise floor of seismometers (Ringler and Hutt 2010).

Table 2 documents some commercially available downhole broadband seismometers to be considered in a selection process.

See company websites for further information.

Downhole Seismic Noise Environment

One of the goals of a seismic station installation is to minimize seismic noise and maximize the level of a seismic signal. In other words, the goal is to maximize the signal-to-noise ratio (SNR) that can be achieved at a seismic station. A higher SNR ratio will enable a station to detect smaller-magnitude seismic events. This goal applies equally to surface vaults and downhole seismic installations, but the means to accomplish this goal are different for vaults and downhole installations due to the characteristics of the seismic noise, the seismic signal, and the local geology.

Downhole Seismometers,
Fig. 3 USGS graphic of seismic noise types

Seismic noise can be broken down into different types or sources of noise. These include wind-induced seismic noise, cultural seismic noise (noise generated by human activities), microseismic noise, moving-water-induced seismic noise, and tilt-induced noise (Fig. 3). Each of these noise sources will be briefly described.

Microseismic Noise

Microseismic noise is caused by wave actions on large bodies of water such oceans, seas, and lakes. As waves enter the continental margins and crash onto shorelines, energy is transferred from the water into the earth, generating Rayleigh waves. Microseismic noise ranges from 1 Hz to 30 s, with a peak at 4–8 s known as the microseismic peak. Microseismic noise is a global phenomenon, but has higher amplitudes closer to coastlines and shorelines.

Tilt Noise

Inertial sensors, such as seismometers, measure accelerations due to the motion of a seismic mass. However, inertial sensors are also sensitive to static accelerations such as gravity. Normally, accelerations due to gravity are counterbalanced by the mainspring in the suspension of a seismometer, but when a seismometer is tilted (rotated around a horizontal axis), gravity

appears as an apparent horizontal acceleration. The resulting accelerations due to tilt are indistinguishable from accelerations due to seismic motion (Rodgers 1968; Graizer 2005). This effect is relatively minor on the vertical axis of a seismometer as long as this axis is substantially vertical. On the horizontal axes, the effect is significant and is described as

$$H = g_0 \cdot \sin \theta$$

Since the angles are small, the approximation $\sin \theta = \theta$ can be used:

$$H = g_0 \cdot \theta$$

where

- $g_0 = 9.8 \text{ m/s}^2$ is the acceleration due to gravity,
- H is the horizontal acceleration in m/s^2 , and
- θ is the tilt in radians.

Ground tilts can be caused by human activities, wind, or changes in local barometric pressure, temperature, or soil moisture content. The magnitude of ground tilts is influenced by the stiffness of the ground. Hard-rock sites will be much less susceptible to tilt as compared to a site

on clay. Tilt noise causes horizontal components to be typically 20–50 dB noisier than the vertical components at long periods (Bormann 2002).

Tilt noise tends to decrease with depth as many sources of tilt noise are surface effects, namely, wind, air pressure, soil moisture, and human activity. Tilt noise can also be caused by air currents circulating around a seismometer. This effect can be significant in borehole installations if strong vertical convection air currents are allowed to flow. Precautions must be taken to prevent the air moving. This problem can be mitigated with a sand installation, which eliminates air spaces around a seismometer, or with insulation methods, such as foam plugs, to limit the airflow below and above a seismometer.

Wind-Induced Noise

Wind is another major source of seismic noise. Wind transfers energy into the ground as it decelerates from colliding with the terrain, water bodies, buildings, vegetation, and other objects coupled to the ground. The chaotic nature of wind often excites resonances in objects it strikes. Trees and buildings sway in the wind, waves are generated on water, and the ground is compressed. Although the wind blows predominantly in a horizontal direction, interactions with the surface translate the motion into the vertical component. For example, as trees sway back and forth in the wind, alternating pressure is placed on opposite sides of the root bundle imparting vertical motion. Wind-induced seismic noise is short period in nature, meaning that is above 1 Hz. Wind noise is dependent on the wind velocity. Higher velocities generate more noise. For reference, a wind speed below 3 m/s (11 km/h) does not raise the background seismic noise at the surface for grassland sites on sedimentary rock in rolling hills (Withers et al. 1996). Wind induces predominantly surface waves (Love and Rayleigh waves) along with a small component of body waves onto the ground.

Moving-Water-Induced Noise

Seismic noise is generated in watercourses from small streams to large rivers. As water flows downhill, turbulence is created which imparts

energy into the ground. Regions with steeper gradients, such as waterfalls and rapids, generate more seismic noise. Moving-water seismic noise is continuous but varies in amplitude depending on water levels. Moving water induces surface waves similar to wind noise.

Cultural Noise

Seismic noise generated by human activities is referred to as cultural noise. The principal sources of cultural noise are related to transportation, construction, military, and mineral extraction activities. However, any human activity can generate cultural noise, even a person walking down a path. Cities have higher levels of cultural noise than rural areas. Cultural noise can be stationary or nonstationary, periodic or random, and generated by sources distributed or localized. Cultural noise does tend to be diurnal, meaning it varies over the day with quietest times in the middle of the night when there is the least human activity. Like wind-induced noise, cultural seismic noise is predominantly composed of high-frequency surface waves but also includes a body wave component.

Seismic Noise Mitigation with Depth

The common factor in wind-induced, cultural, moving-water, and microseismic noise is that the noise is predominately generating surface waves. At short periods, the amplitude of surface waves decays exponentially with depth due to amplitude drop from the surface and due to the upper layers of the earth being highly attenuating or “lossy.” It is well known that high-frequency seismic noise decreases with depth making borehole sites typically quieter than surface vault sites from 1 to 100 Hz (Carter et al. 1991). At long periods, the seismic noise also drops with depth, particularly on the horizontal channels due to a reduction in the tilt noise (Sorrells 1971).

While seismic noise attenuates with depth, seismic signal amplitudes are dependent on a number of factors relating to the geology of the site. As a seismic signal propagates toward the surface, it typically travels through progressively lower Q layers and loses energy. The layers at the surface have the lowest Qs and are responsible for

Downhole Seismometers, Fig. 4 Vault installation and posthole installations at various depths as measured in Ottawa, On, Canada (Nanometrics Inc 2013)

a significant portion of the loss in energy (Aster and Shearer 1991). However, as the velocity of the signal slows, the amplitude increases, and there is also surface amplification effect. In summary, it is difficult to estimate the amplitude of the signal with depth.

Nevertheless, the effect of seismic noise attenuation with depth results in improved signal-to-noise ratios especially when the final layers of earth are highly lossy (Young et al. 1996). Ideally, a downhole seismometer should be placed in hard rock below a highly lossy overburden.

The question that remains is, how deep should the downhole seismometer be placed? The answer is as deep as economically and practically possible as signal-to-noise ratios typically improve with depth in the first few hundred meters. However, the question can be turned around to: how shallow can a downhole

seismometer be placed to result in an improvement in the signal-to-noise ratio? The answer is within 3–10 m of the surface depending on the geology due to the attenuation of temperature, tilt noise, and surface noise.

Consider an extreme example of 15 m clay above quartzite bedrock in an urban environment shown in Fig. 4. This was measured in Ottawa, Ontario, Canada, using Trillium120 Posthole seismometers (Nanometrics Inc 2013). Clay has a very low Q , and the quartzite has a much higher Q . Unsurprisingly, the surface vault has the highest noise at low and high frequencies. The 1.2 m direct burial posthole seismometer installation shows improved low-frequency vertical and horizontal noise and improved high-frequency noise. At 7 m, the posthole seismometer installation shows further improvements in low-frequency horizontal noise and improved high-frequency noise. At 30 m from

the surface in bedrock, the horizontal low-frequency noise has dropped 30 dB, the low-frequency vertical noise has improved 10 dB, and the high-frequency noise on the vertical and horizontal channels has dropped 40 dB as compared to the surface vault. This example shows that improvements in noise levels can be achieved in relatively shallow downhole installations. Deeper installations could possibly yield further improvements, but in this example an improvement was achieved in the first 15 m. It should be noted that these results are specific for this site. In general, noise levels will be site specific.

In summary, even shallow posthole installations can provide SNR improvements over surface vaults.

Downhole Seismometer Installations

Types of Installations

Downhole seismometers can be deployed into boreholes or shallow holes.

Boreholes are steel-cased holes that are cemented into competent rock. Typical seismic boreholes are 50–150 m deep, but there are seismic boreholes 2,000 m deep and beyond (Young et al. 1994). Although a cemented steel casing extends to the surface, a borehole poorly propagates surface noise down the borehole. There are two reasons for this. First, the coupling of the casing to the upper softer layers of material is not as good as the coupling to stiffer materials lower down. Second, the borehole is relatively compliant horizontally over the length of the borehole.

These holes can be drilled using water-well or oil-well drilling equipment. The steel casings are cemented into the borehole to stabilize the casing, provide good coupling to the ground, and maintain the integrity of underground aquifers.

Shallow holes are typically holes 0.5–5 m deep that are dug by shovel or lightweight drilling equipment such as augers, small drill rigs, screw-pile equipment, and the like (Fig. 5). These holes are typically larger in diameter as compared to boreholes to enable a wider range of seismometers to be deployed and to improve access to the seismometer. At permanent sites, the hole may be

cased in steel or pvc and cemented in. Shallow holes drilled into hard rock do not need to be cased. Seismometers are typically deployed into shallow holes using a sand installation method.

Shallow holes that are used for temporary deployments are typically not cased. This minimizes the cost of the installation. A seismometer deployed in an uncased hole is backfilled with sand or the excavated materials from the hole. This type of deployment is also known as a direct burial installation. A direct burial installation is quicker and easier to install than an installation using a vault seismometer. It is often challenging leveling a vault seismometer in a field deployment since it requires a hard surface, access to the leveling feet, and bubble level. With a posthole seismometer, the procedure is to dig a small hole, place the seismometer in the hole, backfill with earth or sand, and start the autoleveling in the seismometer. There is no further work required to insulate or weatherproof the installation.

Seismometer Emplacement

Once a seismometer is lowered into a borehole, it must be secured rigidly in the hole to ensure good seismic coupling to the borehole casing and the ground. There are two methods for accomplishing this. The first is with a mechanical borehole lock and the second is with a sand installation.

A borehole lock is a device attached to the seismometer which clamps the seismometer to the side of the borehole. Typically, a borehole lock has three fixed pins on one side of the holelock which create a three-point contact with the borehole and one moving pin on the opposite side which clamps the holelock to the side of the borehole. The moving pin pushes the holelock three-point contact pins against the borehole with a force sufficient to hold the seismometer in place. The seismometer is then supported by the four pins. This is a kinematic coupling. The seismometer must not be touching the bottom of the borehole; otherwise the coupling will be over-constrained which can result in undesired motions. With this method of locking, the seismometer takes on the vertical angle of the borehole at that point. The moving pin on the holelock

Downhole Seismometers,

Fig. 5 Components of a typical posthole station with the sensor 1–6 m below the surface

can be actuated with an electric motor or a mechanical system controlled from the surface.

The sand installation method involves lowering the seismometer to the bottom of a borehole or shallow hole and pouring dry sand into the hole sufficient to cover the seismometer in sand. The sand flows around the entire seismometer filling the entire gap between the seismometer and the hole. This method of installation has a few benefits and drawbacks. A sand installation is simpler and less costly than a holelock installation. It eliminates convection air currents around the seismometer and effectively couples the seismometer to the casing. However, sand is a loose

material that is prone to spontaneous movements that can be detected by a seismometer during a settling period. Another issue with sand installations is that after a period of time, moisture and dissolved minerals in the sand can solidify the sand making it challenging to remove the seismometer.

Economics of Installations

One of the primary considerations in deploying a downhole seismic station is the cost of the installation, especially in comparison to vault installations. In the past, downhole installations have been substantially more costly than vault

installations because downhole installations were predominately 100–200 m-deep borehole installations with high-cost, top-performance borehole seismometers. A typical borehole was drilled using oil-well drilling equipment which costs approximately US\$100,000 per borehole. A borehole station of this kind would have had a total installed cost of US\$150,000–300,000 depending on the location and ancillary equipment included. This limited borehole installations to those who had budgets large enough to cover cost of a borehole network and had a requirement for excellent signal-to-noise ratios.

Recently, newer instruments and installation methods have dramatically lowered the cost of a downhole installation making downhole stations cost competitive with vault installations.

One of the main innovations is switching away from using oil-well drilling equipment and materials. Oil-well drilling equipment is designed and sized to drill deep wells (up to many kilometers) in complex geologies. This equipment typically includes steerable drill bits to enable horizontal drilling. For a typical vertical seismic borehole of 50–150 m deep, this equipment is expensive to use and in most geologies unnecessary.

Water-well drilling rigs are more suitable and substantially cheaper to operate as compared to oil-well drilling equipment. Water-well drilling equipment is designed for drilling only vertical boreholes 10–300 m deep reducing rig size, complexity, and cost. Water-well drilling services are typically available in most locations reducing deployment costs and are competitively priced due to the demand for water wells. A typical 60 m water well can be drilled in North America for \$US 5,000–25,000.

A seismic borehole includes costs for casing, cementing, and pressure testing, in addition to the drilling costs. Casing and cementing costs will vary with depth, casing type, and diameter. Local drilling contractors who are often very familiar with the geology in the region can readily provide up-to-date prices and guidance on drilling.

For posthole installations, cased boreholes, screw piles, and uncased shallow holes can be

used. Uncased shallow holes are the least expensive and can be dug with hand or powered augers. Screw-pile installations have costs between boreholes and shallow holes. Screw piles are installed with skid-steers and have the added benefit of being removable at the end of a deployment. Local construction contractors can provide current prices for comparison.

Security of Installations

Boreholes and shallow holes are in general more secure than vault installations for the seismometers. The overall footprint of a downhole installation is much smaller and less visible than a typical permanent vault installation and can be camouflaged more easily. If desired, the entire borehole wellhead can be buried. Buried underground conduits can be routed from the borehole or shallow hole to the communications and power hub. The curious would assume that a visible wellhead is that of a water well which is uninteresting. Often winches and tripods (or masts) are required to extract seismometers from the hole providing a level of physical security that is hard to overwhelm even for the most determined thief.

Nevertheless, a downhole seismometer installation only protects half the equipment at the station. The communications and power equipment is still highly visible and attractive to a thief. Solar panels and backup batteries are popular and useful everywhere in the world and are routinely stolen from less-secure sites (see Fig. 6). A solution to station security must cover all the equipment at a site (Fig. 7).

Typically, there is a trade-off to be made between a rural site which has low cultural seismic noise but is less secure due to its isolation and a secure urban site, such as police or fire station, which has higher cultural seismic noise. Ideally, an operator wants a low cultural noise site that is also secure. With downhole installations, a secure urban site enables the reduction of seismic noise by providing vertical separation from seismic noise which originates at the surface. The degree of attenuation of seismic noise with depth will depend

Downhole

Seismometers,

Fig. 6 Rural posthole installation with cellular communications in Alberta, Canada

Downhole

Seismometers,

Fig. 7 Rural vault installation with satellite communications in Fiji

on the local geology and nature of the cultural noise. An urban borehole or posthole may not be as quiet as a good rural site, but it is secure and can be quickly serviced if there is a problem.

A network operator will have to trade security and ease of access for uptime and data quality based on the local geology, cultural seismic noise, economic conditions, cultural norms regarding property, and cost.

Station Footprint

Downhole installations typically have a smaller footprint as compared to vault installations. The land area required for a borehole or shallow hole

can be as little as the area of the hole. Typically, a borehole or shallow-hole installation will require a $0.25\text{--}1\text{ m}^2$ of space (Fig. 9). Seismic vaults typically use much more space, particularly if the vault is a walk-in type of vault.

The smaller footprint of a downhole site offers more flexibility in station placement, especially in an urban environment where available land is limited and costly and local building codes restrictive.

Site Environmental Conditions

The site environmental conditions, namely, weather, water, and wildlife, have a large impact

Downhole Seismometers,

Fig. 8 Ground temperature variations with depth for Ottawa reproduced from Williams and Gold (1976)

on the performance of seismic stations. While great care must be taken with the design of vault installations to mitigate the effects of temperature, wind, air pressure, water egress and flooding, and wildlife, downhole installations are much less susceptible to these effects and require less design effort.

Temperature

Seismometers are sensitive to temperature changes, and ideally, a seismometer should be exposed to as little temperature variation as is economic. At the surface, the temperature can range from -20°C in the winter to $+35^{\circ}\text{C}$ in the summer in a northern continental climate, with daily fluctuations between 10°C and 20°C . Other climates can be more or less extreme. A vault installation uses thermal insulation and structures with high thermal mass to reduce the temperature variation of the seismometer. This requires design work and cost.

A downhole installation relies on the heat capacity and thermal conductivity properties of the ground to reduce the temperature fluctuations to a minimum. The depth where the temperature fluctuation is 1/100 of the surface temperature variation for a given time period is known as the

penetration depth and depends on the composition of the soils and the moisture content of the soils. For daily temperature variations, the penetration depth is less than 1.2 m for all soil types. The yearly penetration depths vary from 5 to 20 m depending on the soil conditions. For most downhole seismometer installations, an annual temperature variation of $\pm 3^{\circ}$ is acceptable and can be achieved in as little as 3–6 m below-ground. See Fig. 8; ground temperature variations with depth for Ottawa, reproduced from Williams and Gold (1976).

Water Egress

Seismic vaults are usually located at or just below the surface on undisturbed soils and are subject to water egress and flooding from time to time. While vaults are often designed to be waterproof, there is usually some weakness in the implementation that enables water to enter the vault over time or during flood situations. Some vaults are equipped with pumps, but over time, pumps fail. This would not be an issue except that vault seismometers and ancillary equipment are not designed for continuous submersion. Flooding causes the temporary shutdown of many vault seismic stations.

Downhole Seismometers, Fig. 9 Rural borehole seismometer deployment in Alberta, Canada

Downhole seismometers are designed for continuous submersion and are unaffected by periodic flooding. Generally, boreholes and postholes are designed to be dry, but it is not strictly necessary for the equipment. Shallow hole can be dry or wet, or even below the water table. Water may degrade the seismic performance due to movement of the water, but it will not cause the total loss of data from a station.

Wildlife

Animals from time to time cause problems at seismic stations. This can range from large animals walking in the vicinity of the station or scratching themselves against the station down to mice building nests in the insulation surrounding a seismometer or chewing cables and every critter and its activities in between. Being at the surface, vault installations are simply more accessible and susceptible to these invasions. Downhole Installations are away from the surface and difficult to access

even for the smallest animals. Surface noise from animals is attenuated with depth to some degree.

Deployment Considerations

Borehole Verticality

Boreholes are typically not vertical holes but have small tilt angles of up to 10° from vertical. This is due to the accuracy of the driller's equipment and technique and the nature of the material being drilled. Drilling practices that affect the verticality of a borehole include the weight on the drill bit, the speed of drilling, the degree of hole cleaning, drill bit selection, whether a steerable drill bit is used, and the use of verticality monitoring equipment while drilling. Experienced drillers understand the trade-offs in maintaining a vertical borehole. In maintaining a vertical borehole, a driller will want to understand the geology of the area prior to drilling. It is harder for a driller to maintain verticality with complex borehole profiles. For example, it is more challenging to maintain verticality when drilling soft sediments such as clay or sand or in sediments with materials with differing hardness such as glacial till or limestone with cavities. With glacial till, the drill bit can be deflected by rocks and boulders in the sand, and with limestone, the drill bit can drift in the cavities. Other challenging borehole profiles include highly fractured rock and sedimentary rocks with steep dip angles.

In most situations, drillers can maintain the tilt to less than 3° off vertical. Typically, drilling specifications stipulate that the borehole shall be within 3° off vertical or less. USGS suggests a drilling specification of 2° or less (Albuquerque Seismological Laboratory 2001). Even with a vertical error of 3° , the vertical offset or drift at the bottom of the 100 m borehole is just over 5 m. The drift at the bottom of a borehole may be a concern in some installations that have underground features that must be avoided.

Another issue related to borehole verticality is the tilt of the seismometer in the borehole. It is not possible to maintain the verticality of a

seismometer as it is lowered; a seismometer will always be resting against the side of the borehole as it goes down and will tend to assume the angle of the borehole when it reaches the bottom. For example, if the seismometer is lowered to 50 m in the borehole, and the borehole at 50 m is 2° off vertical, the seismometer will tend to be 2° off vertical when it comes to rest. See section “[Levelling](#)” for how to compensate for the vertical error.

Aligning to North

Seismometers are typically aligned to north. Vault seismometers are aligned to north manually using a compass. A compass bearing is taken, a north–south line is scribed on the vault floor, and the seismometer is manually rotated to align with the north–south line. There are many variations of this method, but overall the process is straightforward.

Aligning downhole seismometers to north is more challenging. The user has only limited access to the instrument downhole, and a compass cannot be used downhole due to the magnetic shielding by the steel borehole casing. Nevertheless, methods have been developed to align downhole seismometers.

The downhole alignment process can be broken down into two steps. The first step is to determine the seismometer orientation relative to north. This can be accomplished using a number of different methods including downhole gyroscopic alignment, surface seismometer referencing, rifle scope alignment, and north-finder alignment. See below:

- With gyroscopic alignment, a gyroscope is activated and aligned to north at the surface. It is then lowered down the borehole and engages with a north-aligned feature on the seismometer or holelock. A reading is taken from the gyroscope to determine the rotational offset from north.
- Surface seismometer alignment involves collecting a seismic data set from the downhole seismometer and a surface seismometer located at the wellhead. The downhole data set is

correlated with the surface data set to determine the offset from north.

- Rifle scope alignment involves mounting a rifle scope vertically pointing down the borehole. The rifle scope cross hair is focused on the north–south marking on the seismometer downhole. A reading of the rifle scope rotation relative to north is taken.
- North-finder alignment uses a north-finder instrument which measures earth’s rotation vector to determine north. The north finder can be mounted on the seismometer or lowered down the borehole to engage the seismometer.

The second step is to rotate the seismometer to be north aligned. This can be done digitally, mechanically with a “bishop’s hat” mechanism, or manually with an alignment rod.

- Digital alignment involves mathematically rotating the digital data set to align to north. This can be done with no loss of precision. The user enters a rotation parameter into the seismometer or digitizer configuration, and the instrument subsequently rotates all time-series data.
- Bishop’s hat mechanical alignment is a multistep process. A holelock with a bishop’s hat mechanism is lowered into the borehole and clamped in place. A north-measuring device is lowered onto the bishop’s hat mechanism to determine the orientation of the holelock. The north-measuring device is removed, and the seismometer bishop’s hat mate is rotated and locked at the surface. The seismometer is lowered down onto the bishop’s hat and is now aligned to north. A bishop’s hat mechanism is a device that forces the mating assembly (the seismometer) to a particular orientation. It is called a bishop’s hat because it is shaped like a bishop’s hat.
- Lastly, a seismometer can be aligned with an alignment rod. The alignment rod is attached to the seismometer and the seismometer is lowered into the hole. From the surface, the user rotates the alignment rod and the

seismometer together. Once the seismometer is aligned, the alignment rod is removed from the hole. An alignment rod is limited to use in postholes and shallow holes.

Summary

In the past, downhole seismic stations were limited to deep borehole installations which were so expensive that they only justified the deployment of very costly borehole seismometers. These stations demonstrated the reduction of seismic noise and the improvement of signal-to-noise ratios with depth. However, the cost of ownership of these stations limited their widespread adoption.

In the last few years, posthole and direct burial seismometers have been introduced, a better understanding of seismic noise and its dependence with depth has been developed, and more economic installation methods, such as those using water-well drilling equipment, have been established. These instruments and methods have made downhole seismometer installations cost competitive with vault installations, while at the same time improving on the signal-to-noise ratios. In some cases, downhole installations can cost much less than vault installations of similar performance.

Shallow-hole direct burial deployments are an improvement over temporary surface deployments in many aspects. These include improved signal-to-noise ratios, better site security, simpler installation and servicing, smaller footprint, and improved station reliability.

With new borehole and shallow-hole deployment methods feasible, network operators can now balance more finely the cost of a downhole station with the quality of the seismic data enabling operators to collect better data for less money.

Synonyms

Drift; Earthquake records; Long-distance effects; Long-period structure; Tohoku earthquake

Introduction

One of the most significant effects of the M9.0 Tohoku, Japan, earthquake of March 11, 2011, is the now well-known long-duration (>10 min) shaking of buildings in Japan – particularly those in Tokyo (~350–375 km from the epicenter) and in places as far as Osaka (~770 km from the epicenter). Although none collapsed, the strong shaking caused many tall buildings not to be functional for days and weeks.

The purpose of this entry is to discuss the drift ratio issues related to tall buildings in Japan affected by long-period ground motions at far distances from the epicenter of the Tohoku earthquake of March 11, 2011 ($M = 9.0$). We review the inferred long-period long-distance effects of the ground motions from recorded response data from four tall buildings in Osaka and Tokyo and the spectral properties of ground motions recorded from stations nearby these buildings.

Therefore, three other relevant topics are also discussed in this entry:

- (a) Past observations of long-distance long-period effects and implications for the United States
- (b) Long-period effects as demonstrated by response spectra of ground motions recorded during the same event
- (c) Maximum allowable drift ratios in Japan and other seismic areas of the world

The performances of buildings discussed in this entry are inferred from computations of average drift ratios because the accelerometer deployed in the tall buildings is sparse. It is important to note that drift ratios are the best measure to infer damage occurrence or likelihood during design/analysis processes and also during analyses of recorded response data if they exist (Çelebi et al. 2004; Çelebi 2008). The effect of long-period ground motions to buildings and other long-period structures is demonstrated by the four cases presented herein.

All of the four examples indicate that considerably higher drift ratios for relatively low (~3 % g) to moderate (10–20 % g) input ground motions were affecting the functionality of tall buildings at large distances from the epicenter of the Tohoku event. Published documents to date on performances of tall buildings during the Tohoku event in general do not describe actual observed or unobserved possible hidden damages. While no collapses were reported, there is no certainty that hidden damages in some of the buildings do not exist.

Past Observations of Long-Distance Long-Period Effects and Implications for the United States

One of the earliest observations in the United States was during the $M = 7.3$ Kern County earthquake of July 7, 1952 that shook many taller buildings in Los Angeles and vicinity, about 100–150 km away from the epicenter (http://earthquake.usgs.gov/earthquakes/states/events/1952_07_21.php, last accessed July 15, 2011; Hodgson 1964). The March 28, 1970, $M = 7.1$ Gediz earthquake in inland western Turkey damaged several buildings at a car-manufacturing factory in Bursa, 135 km northwest from the epicenter (Tezcan and Ipek 1973). One of the most dramatic examples of long-distance effects of earthquakes is from the September 19, 1985, Michoacan, Mexico, $M 8.0$ earthquake during which, at approximately 400 km from the coastal epicenter, Mexico City suffered more destruction and fatalities than the epicentral area due to

amplification and resonance (mostly around 2 s) of the lakebed areas of Mexico City (Anderson et al. 1986; Çelebi et al. 1987). To the best knowledge of the authors, however, there are no publicly available records of the responses of tall structures from these past earthquakes. Therefore, records obtained from numerous instrumented tall buildings during the Great East Japan earthquake of March 11, 2011 offer a rare opportunity to study and understand how structures characterized by predominantly long-period responses behave during medium to large events originating at long distances. Such effects have consequences for large metropolitan areas in Japan but also in other parts of the world, including the United States (e.g., Los Angeles area from Southern California earthquakes, Chicago from NMSZ, and the Seattle (WA) area from large Cascadia subduction zone earthquakes). For example, the recent $M = 5.8$ Virginia earthquake of August 23, 2011, was felt in 21 states of the Eastern and Central United States that include large cities such as New York and Chicago (<http://earthquake.usgs.gov/earthquakes/eqinthenews/2011/se082311a/#summary>, last accessed September 11, 2014). During this event, occupants of a 28-story building at MIT Campus in Cambridge, MA, experienced the shaking (Toksoz, 2011, “personal communication”).

Discussion on Long-Period and Long-Distance Effects During Tohoku Earthquake and Response Spectra Issues

Based on a study by Okawa and others (2010), 4 months before the Tohoku event, the Japanese Government Ministry of Land, Infrastructure, Transport and Tourism [MLIT] released a regulation to upgrade the design of high-rise buildings under long-period ground motions (2010). With this release, MLIT solicited public and professional opinions. However, immediately after the end of this period, the Tohoku earthquake occurred. Following the Tohoku event, MLIT started to revise the document with collected opinions and new data from the earthquake.

In the MLIT (2010a) document, a total of 9 areas in Japan were specified (4 in Tokyo, 3 in Nagoya, and 2 in Osaka). For each one of these areas, simulated acceleration and velocity time-histories were specified. Takewaki and others (2011) report that velocity response spectra of all the simulated ground motions have significant large peaks within 2–8 s range. It is important to state that Takewaki and others (2011) report that in Shinjuku area of Tokyo, where tall buildings are discussed later in this entry, the KNET Shinjuku station (TKY007) motions exhibit predominant peaks between 3 and 8 s range.

In this entry, we present acceleration and velocity response spectra of ground motions recorded during the Tohoku earthquake from two stations. As an example, for Osaka Bay, spectra of motions from KIKNET station OSKH02 are provided in Fig. 1 and display the long periods both at surface and downhole. This station is closest to the example building in Osaka Bay discussed also later in the entry. In Fig. 2, we present spectra of motions from KNET stations TKY007 (representative of motions in the Shinjuku area of Tokyo, as discussed above). These spectra clearly display the long periods capable of affecting responses of the tall buildings. TKY007 was also examined by Takewaki and others (2012).

Drift Ratios of Different Countries

Before presenting drift issues relative to the four buildings, it is important to review practiced drift ratio limits of a few seismically active countries and also that of Eurocode 8 (2008). Comparison of the drift ratios of five countries and Eurocode 8 is provided in Table 1. The table exhibits drastic variability in practice of drift ratio limits from 0.2 % to 2.5 %.

Buildings Studied

Building A at Osaka Bay ~ 770 km from the Epicenter of the Earthquake

Detailed discussion of the building, data, and analyses is provided in Çelebi et al. (2012).

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 1 (Left) NS and EW acceleration response spectra and (right) velocity response spectra of ground motions recorded at surface and downhole during Tohoku

event at KIKNET OSKH02 station in Osaka Bay. Velocity response spectra exhibit the large amplitudes between 5 and 7 s

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Fig. 2 (Left) NS and EW acceleration response spectra and (right) velocity response spectra of ground motions recorded during Tohoku event at KNET

TKY007 station in Shinjuku area of Tokyo where tall buildings are concentrated. Velocity response spectra exhibit the large amplitudes particularly for periods >2 s

Figure 3 shows vertical sections and locations of triaxial accelerometers. Figure 4 shows plan views, orientation of the building, and location of accelerometers at the 52nd floor.

The building was subjected to an input motion at ground level with peak accelerations of $\sim 3\%$ g during the Tohoku earthquake. Furthermore, the building was founded at a site with a site frequency (period) of 0.13–0.17 Hz (5.88–7.69 s) as seen in Fig. 5 (left) (Çelebi et al. 2012).

The parameters used in computing the site transfer functions are the (depth vs. Vs) Profiles A, B, and C shown in Fig. 3 (left). Profile A is an approximation based on the geotechnical data for free-field KIK-NET station OSKH02 that is near (~ 2.5 km) the building. In this profile, the upper and softer layers have been ignored. By way of comparison with the transfer functions computed for Profiles B and C, which underlie the building, it is concluded that the upper layers

Drift Issues of Tall Buildings in 2011 Tohoku Earthquake, Table 1 Upper limits of drift ratios (Japan, Chile, the United States, Turkey, New Zealand, and Eurocode 8)

Code of	Upper limit drift ratio (%)	Comment	Reference
Chile	0.2	Results in elastic design	NCh433.Of96 (1996)
Japan	1.0	Max for buildings taller than 60 m. For collapse prevention (level 2) motions	Building Center of Japan 2001a, b
The United States	2.0	No collapse state	ASCE7-10 (2007)
Turkey	2.0	Can be increased by 50 % in case of some steel frames	DBYYHY (2007): Section 2.10.1.3, Eqn: 2.19 in Turkish Code (2007)
New Zealand	2.5		NZS1170.5(2004)
Eurocode 8	1.0 (max)	For buildings having nonstructural elements fixed in a way so as not to interfere with structural deformations or without nonstructural elements	Section 4.4.3.2, Eqn: 4.33 Eurocode 8 (2008)

do not significantly alter the computed fundamental frequency of the site of this building. Q values used in calculating the transfer functions range between 25 and 60 for shear wave velocities between 200 and 600 m/s – having been approximately interpolated to vary linearly within these bounds. As seen in Fig. 5 (left), the site fundamental frequency is computed to be in the range of 0.13–0.17 Hz due to the dominant characteristics of layers three and four (typically of the area of the site of the building and KIKNET OSKH02 strong-motion station as described in Fig. 5 [left]).

The building exhibited fundamental frequencies (periods) of 0.152Hz (6.58 s) in the X-direction and 0.145 Hz (6.90) in the Y-direction as seen in Fig. 5 (right). Such close frequencies are clear confirmation of resonance that led to prolonged responses (~1,000s recorded) and long-duration high-amplitude shaking as exhibited in Fig. 4 which shows average drift ratios.

The average drift ratios (Fig. 6) computed from relative displacements between many floors indicate that maximum average drift ratios experienced during the mainshock were between 0.5 % and 1.0 % for the X-direction and 0.2–0.4 % for the Y-direction. These average drift ratios are less than the maximum 1 % limit usually used in Japan for collapse protection level motions (level 2 used for buildings 60 m

or taller (The Building Center of Japan 2001a, b)). However, average drift ratios are much larger than expected for an input motion with a small peak acceleration in the order of only 3 % g. In the United States, the comparative maximum drift ratio for tall buildings for Risk Category 1 or 2 is 2 % (Table 12.12, ASCE7-10 2007).
